Congenital Heart Defects

DECISION MAKING FOR SURGERY

3 CT-Scan and MRI
Dedicated to our loved children
Federica, Laura, Jonathan, Bean
Laura, Paula, Pablo, Kiko
The diagnosis and management of congenital heart disease has evolved rapidly over the last 30 years. In the 1970s, invasive cardiac catheterization was a high-risk procedure for the infant and particularly the duct dependent neonate. The introduction of noninvasive 2-dimensional echocardiography revolutionized the diagnosis and management of individuals with congenital heart disease. No longer was the cardiologist limited to a handful of images and patient positions but could spend hours if necessary defining every detail of an individual child’s cardiac anomaly. The addition of Doppler and subsequently color Doppler further increased the importance of echocardiography in the decision making for congenital cardiac surgical procedures. And now we are fortunate to have further additions to the imaging and diagnostic armamentarium, namely cardiac CT and cardiac MRI.

In this most recent volume of the series entitled “Congenital Heart Defects: Decision Making for Surgery” Dr. Antonio F. Corno provides an up-to-date and comprehensive presentation of the new role that cardiac CT and cardiac MRI will play in the management of congenital heart disease. He has been ably assisted by a cardiologist, Dr. Gigi P. Festa.

The book provides a dazzling array of images derived by both techniques and covering the full range of congenital heart anomalies. Both the pre-operative and postoperative usefulness of these techniques is presented.

There is no doubt that these techniques will be particularly helpful in the older child and adult with congenital heart disease in assessing the late impact of a congenital heart anomaly and the surgical repair or palliation which may have been undertaken years previously.

The time is definitely right for a comprehensive presentation of these new diagnostic modalities and the manner in which they will influence the field of congenital heart management.

Dr. Corno is to be congratulated on seizing this opportunity and producing a beautifully illustrated textbook that will be the standard against which others will be measured.

Washington, DC  RICHARD JONAS, M.D.
August 2008
Preface

The first two volumes of this series on “Congenital Heart Defects – Decision making for surgery” have been dedicated to the “Most common defects (Volume 1)” and to “Less common defects (Volume 2)”. The schema utilized for these two books was the same, with each chapter devoted to a single malformation, with incidence, morphology, associated anomalies, pathophysiology, diagnosis (including clinical pattern, electrocardiogram, chest X-ray, echocardiogram, and cardiac catheterization with angiography), indications for surgical treatment, details of surgical techniques, potential complications and literature references.

During the last few years computed tomography (CT) scan and magnetic resonance imaging (MRI) have emerged as valuable noninvasive cardiovascular diagnostic tools. Both CT scan and MRI are capable of producing stunning 3-dimensional pictures independent of body size. In particular cardiac MRI can provide unique anatomic and functional information not available by any other diagnostic modality previously available. Because of the progressively increasing role of CT scan and MRI in the pre- and postoperative evaluation of patients with congenital heart defects, it seemed natural to continue this series of volumes preparing a third book entirely dedicated to these two diagnostic techniques.

The sole author of the first two volumes (AFC) decided to involve Dr. Gigi P. Festa, cardiologist with extensive expertise particularly in cardiac MRI, in the current task. The choice was due not only to his competence in the matter, but to the fact that we worked together years ago, first in Milan, Italy, then in Paris, France, with Dr. Yves Lecompte. The mutual respect that develops among colleagues is not enough to write a book, particularly when working as nowadays in different departments and living in different countries, with different professional schedules and family commitments, despite the advantages of the communication feasible through the internet. A deep friendship is indispensable to reach agreement on every single detail, including the entire text and the choice of illustrations.

We agreed to maintain the extremely schematic format of the book, following the style of the first two volumes, in order to provide the essential information to the readers. Since our list of congenital heart defects is derived from the sum of malformations treated in the first two volumes in this series, most of the clinical data on conventional diagnostic techniques (electrocardiography, X-ray, echocardiography, cardiac catheterization with angiography), indication for surgery and surgical techniques have been omitted to avoid duplication with the other volumes of the series. Only a selected num-
ber of illustrations, as well as number of references, could be used because of space limitations. Finally, since the pre-operative and post-operative illustrations are coming from different departments and different periods, it is quite clear that the patients have been treated with either interventional cardiology or surgical techniques by different operators, not necessarily by the authors.

Liverpool and Massa, Summer 2008

ANTONIO F. CORNO
GI GI P. FESTA
Since this book is the result of our combined experience, we would like to thank all the individuals who contributed to developing our current knowledge in the field of congenital heart defects.

Acknowledgement begins with all the sick children encountered during our professional lives, and also their families, who gave us the permission to publish the images obtained from the investigations on their children. Then to all the colleagues, nurses and technicians who have participated in the pre-operative, intraoperative and postoperative care of all the patients, and of course to all the individuals (colleagues, technicians, nurses, secretaries) involved in the CT scan and MRI investigations, mostly performed at the Radiology Department of Alder Hey Children’s Hospital, Liverpool, and the MRI Laboratory of Institute of Clinical Physiology, CNR, Pisa.

This book has been stimulated by the pioneering work of Dr. Tal Geva, Boston, who not only opened the pathway towards the investigation of congenital heart defects with these new diagnostic techniques, but was able to transmit the passion for the know-how thanks to his very extensive knowledge, didactical capability and passionate approach.

Special mention is addressed to Dr. Mohamed Tawil, Consultant Pediatric Radiologist and to Dr. Robert A. Johnson, Consultant Pediatric Cardiologist, Alder Hey Hospital, Liverpool, both with a special interest in pediatric cardiothoracic imaging, who were available to help not only in the selection of the illustrations, but also in reviewing part of the text. In particular Dr. Mohamed Tawil is responsible for all the pre- and postoperative investigations in the pediatric cardiac patients in Alder Hey Hospital.

Another special mention goes to Dr. Lamia Ait-Ali, Cardiologist at Pasquiniucchi CNR Hospital, Massa. Thanks to her extensive experience with imaging post-processing and to her tireless dedication, she made a major contribution to preparing this book.

Special thanks are extended to Prof. Luigi Donato, Director of the C.N.R./Regione Toscana Foundation, whose whole life has been dedicated to the development of a particular environment with combined clinical activity and research in cardiopulmonary diseases, leading to the setting of the MRI Laboratory in Pisa, one of the few in Europe fully dedicated to cardiac investigations including congenital heart defects.

Strong encouragement to complete the book came from eminent pediatric cardiologists, including Roberta G. Williams and the late William F. Friedman from Los Angeles, California, and from Bruno Marino, Rome.
Also pediatric cardiac surgeons were very supportive of the idea of a book dedicated to pre- and postoperative CT scan and MRI of congenital heart defects, in particular Aldo R. Castañeda, Guatemala City, Yves Lecompte, Paris, and Richard A. Jonas, Washington, D.C., who very kindly contributed the Foreword.

Everyone from the Publisher’s side has to be acknowledged, in particular Susanne Denskus and Annette Gasser, because of their patience and compliance with our increasing requests for more space for both text and illustrations.

Two companies were instrumental in supporting part of the costs of publication: Philips UK (in particular Alistair Howseman) and General Electric Italy (in particular Roberto Molinari).

We apologize in advance for any omissions or mistakes that might be called to our attention.

As a profession constitutes only a part of our life, we deeply acknowledge our families’ unconditional support, particularly the patience from our wives Josie and Arantxa for the long hours spent evenings and on weekends working to complete this book.

Introduction

Transthoracic echocardiography is the first-line imaging modality for diagnosis and follow-up of patients with congenital heart defects due to its low cost, widespread availability, portability, ease of use, and excellent temporal-spatial resolution, reducing the need for diagnostic cardiac catheterization and angiography in most patients. However, the diagnostic utility of echocardiography markedly diminishes with the growth of the patients and after surgical procedures through median sternotomy because acoustic windows become progressively more limited. Moreover extracardiac structures, such as the great arteries and great veins, complex intracardiac connections or surgically implanted conduits or baffles deeply located in the chest or behind the sternum, may also be difficult to resolve by ultrasound. Diagnostic cardiac catheterization carries risk of complications because it is invasive and is associated with radiation exposure; furthermore as a projection technique, it is limited in providing accurate anatomical information. In the last two decades, computed tomography (CT) scan and magnetic resonance imaging (MRI) have emerged as valuable noninvasive cardiovascular diagnostic tools capable of producing informative pictures, providing unique anatomic and functional information not available by any other diagnostic modality currently available. For the assessment of the anatomy of the extracardiac structures, the clinical indication for CT scan and MRI are somewhat similar, and very often the question which is better to use is raised. The main differences as well as advantages and disadvantages are highlighted in Table 3.0.1.

The easy of use and the short time required for the complete investigation make the CT very attractive, particularly in children. However, according to the recent literature, its radiation exposure represents a major concern, mainly in children and its use should be limited whenever possible as recommended by the FDA in 2001. While the CT scan still remains a very valuable tool to provide detailed information about extracardiac structures, the available clinical experience with MRI is becoming richer than that with CT due its better capacity to assess intracardiac morphology and cardiac function, and its better versatility.

The choice between CT and MRI has to be based on the available institutional equipment and scheduling, the capability of the

patient to cooperate, and the need to tailor the investigation to answer the specific question being asked. Cardiologists and radiologists should be provided accurate estimates of CT radiation doses to allow for a balanced and accurate assessment of the risk/benefits ratio when considering indication for a CT scan.

**Computed tomography**

**General principles**

Computed tomography (CT) is a medical imaging method using tomography where digital geometry processing generates a 3-dimensional image from a large series of 2-dimensional X-ray images. Although historically the generated images were in the axial or transverse plane, orthogonal to the long axis of the body, modern computational techniques allow this volume data to be reformatted into various planes or even as 3-dimensional representations. CT has undergone staged evolution leading to increased spatial resolution and temporal resolution. Initial single slice CT has evolved into helically scanning CT in which large volumes could be included by the translation of the subject along the axis of scanner. By introducing multiple detectors (multislice CT) including arrays detectors, commonly 64 in the current clinical practice, increased resolution and/or volumes can be imaged on shorter time scales. This has led to the ability to perform high-resolution scans gated to the cardiac cycle.

**Patient preparation**

The need of sedation in infants and children less than 6 years of age has decreased as the speed of CT scanning has increased. While the sedation rate for single-detector row CT was at least 30%, the sedation rate for young children undergoing multidetector row CT is less than 5%. Despite this improvement, sedation has not yet been eliminated, and knowledge of safe and effective use of sedation remains of paramount importance.

Oral administration of chloral hydrate is used as a sedative agent in children, while deep sedation (propofol) or general anesthesia (isoflurane) is used in infants. In older children adequate preparation with verbal reassurance and explanation of the procedure can generally obtain good cooperation.

**Methodology and technical aspects**

**Intravenous contrast material**: The issues in the administration of intravenous contrast material for CT angiography in pediatric patients include type and volume of contrast material, method of administration (manual versus power injection), and delay between the start of injection and the initiation of scanning. Intravenous contrast material is not required for routine investigation of the airways, but is essential in children with suspected para-tracheal malformation such as vascular rings or pulmonary artery slings. Through an intravenous cannula placed in the CT suite, the nonionic contrast material is administered at a dose of 2.0 mL/kg. The use of a nonionic agent minimizes the gastrointestinal side effects such as nausea and vomiting, the discomfort at the site of injection, the patient reaction during the administration of intravenous contrast material, and potential complications from contrast material extravasations. With multidetector row CT volumes as small as 2 mL/kg allow successful contrast enhancement for CT angiography. Intravenous contrast material can be administered by manual (hand) or power injection. The advantages of power over manual injection are the ability to precisely determine the timing of delivery of the contrast material and the uniformity of enhancement. The flow rates vary with the size of the intravenous catheter, from 1.5 to 2.0 mL/s for a 22-gauge catheter to 2 to 3 mL/s for a 20-gauge catheter. During the injection
of contrast material, the site of injection needs to be closely monitored to minimize the risk of extravasations. As a general rule the contrast material is administered with a flow rate calculated to deliver the entire volume of contrast material in a period equivalent to, or slightly less than, the duration of the CT acquisition. There is a low but non-negligible level of risk associated with the intravenous administration of the contrast agent itself: severe and potentially life-threatening allergic reaction and renal insufficiency. Because of these risks, ionic contrast agents are generally avoided.

- **Scanning delay time:** The time between the start of the injection of contrast material and the start of the scan data acquisition is the delay time. Empirically the duration of the scanning time should be set to obtain the maximum of contrast concentration in the region of interest, in order to provide excellent vascular enhancement in children. An automated tracking system, taking into account variable factors such as cardiac output and circulation time, allows customization of contrast enhancement for each individual patient.

- **Technical parameters:** Before scanning is started, several technical parameters have to be selected, including collimator thickness, table speed, tube current or milliamperage, kilovoltage, and anatomic coverage required. Sections of 1 mm thickness are generally used in children, to maintain accurate definition without increasing the radiation dose. The table speed is set as fast as possible to increase the temporal resolution and to decrease the radiation combined with detector array dimensions. Electrocardiographic gating is able to reduce artifacts related to cardiac motion and arterial pulsation, but it does not affect the respiratory motion.

- **Radiation exposure:** In children the issue of radiation exposure is extremely important. Since children's organs are more radiosensitive than adults' and they have a longer life span than adults, the development of radiation-induced malignancies is a real potential risk, particularly in younger children. On average, the radiation exposure during a CT scan reaches 2.0 to 2.5 rems, in comparison with 1.5 to 2.0 rems during a diagnostic cardiac catheterization with angiography. The radiation dose for a particular CT study depends on multiple factors: volume scanned, patient size, number and type of scan studies, and desired resolution and image quality. In general, multidetector row CT should be performed with techniques providing adequate quality of images with the lowest possible radiation exposure. These techniques include the use of the lowest milliamperage and kilovoltage settings, appropriate section thickness, and the fastest table speed. Adjustments of specific technical factors proved to minimize the radiation dose in children undergoing CT, particularly in state-of-the-art multissection spiral CT: such adjustments include setting the lowest diagnostic tube current according to the patient's weight and doubling the pitch, which reduces the radiation dose by half. The use of ECG prospective gating in multislice CT scan allows a further reduction of the radiation exposure, thanks to the acquisition of images limited to 70–80% of the R-R interval. In addition, multiphase studies should be used for selected indications rather than on a routine basis.

- **Anatomic coverage:** A minimal coverage for CT angiography should extend from the level of the diaphragm inferiorly to just below the thoracic inlet, in order to include the proximal aspects of the common carotid arteries and of the subclavian arteries in the CT scan. This inclusion allows visualization of the position of the aortic arch, presence of aortic coarctation, presence and degree of hypoplasia of the aortic arch, and anomalous origin of the head and neck vessels. The selected field of view has to approximate the cross-sectional size of the region being studied. A smaller field of view can reduce a waste of matrix space, a loss of resolution, and incidence of poor quality images.
**Breath holding:** CT scan investigations are performed with breath holding at suspended inspiration in cooperative grown-up children and during quiet respiration in children under sedation.

**Reconstruction algorithms:** A standard reconstruction algorithm is generally enough in routine CT angiography studies. A high resolution algorithm is used for 3-dimensional reconstructions involving the airways.

**Post-processing applications**

Various options are available for post-processing the volumetric data set.

**Multiplanar reconstructions:** Sections of multiplanar reformations can be displayed in any plane: coronal, sagittal, parasagittal or in curved isotropic datasets, such as along the axis of the mediastinal vessels or airways. This technique is fast and can be easily performed at the CT scanner, but it provides only a 2-dimensional display of data (Figs. 3.0.1...)

---

**Fig. 3.0.1.** CT scan of normal anatomy. a Axial section of a 2-dimensional study showing the relationship between the great arteries. b Para-coronal plan of a 2-dimensional study showing the relationship between the great arteries, in the presence of situs solitus, with the liver on the right side and the stomach on the left side (AAo ascending aorta, DT Ao descending thoracic aorta, LPA left pulmonary artery, MPA main pulmonary artery, RPA right pulmonary artery, LV left ventricle, PA pulmonary artery)

**Fig. 3.0.2.** CT scan of normal coronary arteries. CT angiography with axial (a) and coronal (b) projection showing the normal origin and course of right and left coronary arteries, respectively, from the right and left aortic sinus (LAD left anterior descending coronary artery, LCA left coronary artery, LCX left circumflex coronary artery, RCA right coronary artery) (reproduced with permission from Goo HW, Park IS, Ko JK, Kim YH, Seo DM, Yun TJ, Park JJ, Yoon CH (2003) CT of congenital heart disease: normal anatomy and typical pathologic conditions. Radiographics 23:S147–165)
and 3.0.2), and information regarding the 3-dimensional spatial relationship of anatomic structures is absent. Curved planar reconstructions are a variant of the routine multi-planar reconstructions, allowing curved or tortuous vessels such as the aorta and the pulmonary artery to be visualized in a single tomography volume.

**Variable-thickness displays:** With this technique, CT images are acquired at their routine thickness section, and then combined in multiples (“slabs”) to create a thicker image. This allows better visualization of smaller pulmonary vessels and airways.

**3-Dimensional volume rendering:** Volume rendering has largely replaced other 3-dimensional reformatting techniques, because the use of a transfer function allows mapping of a CT number to brightness and color. This provides valuable information regarding the spatial relationship of anatomic structures, and it also allows the data to be displayed from an external or internal perspective. The volume-rendering technique is particularly useful for structures which are 3-dimensional and cannot be easily captured in a planar image (Fig. 3.0.3). The creation of volume-rendered images requires secondary processing, and the images can generally be produced in a few minutes.

**Magnetic resonance imaging**

**General principles**

Cardiac MRI in the pediatric population is accompanied by a unique series of technical challenges superior to those encountered in imaging of adult patients: the anatomical structures are smaller, thus, demanding greater spatial resolution; the heart rates are generally higher, requiring a greater temporal resolution; and the pediatric patients can be either noncooperative or may require full sedation. Despite these technical difficulties,
cardiac MRI offers several characteristics favorable in comparison with the conventional imaging modalities, including soft tissue contrast, capacity for true 3-dimensional imaging, accurate flow measurements, freely selectable imaging planes, and lack of ionizing radiation. These advantages, in addition to continued advances in MRI hardware, software, and imaging techniques, are progressively increasing the widespread utilization of cardiac MRI in pediatric cardiology.

Through the use of several MRI techniques, examiners can obtain high-quality 3-dimensional images of the cardiovascular anatomy, accurately quantify volumes and mass of cardiac chambers, ejection fraction, stroke volumes, regurgitation volume and fraction, as well as regional left and right ventricular myocardial function. Therefore, MRI is ideal for noninvasive pre-operative evaluation of patients with complex intracardiac anatomy, anomalous connections of the systemic and pulmonary veins, anomalous pulmonary arteries, defects involving the aorta and its branches, single ventricles, systemic right ventricles and abnormally shaped left ventricles. MRI has also acquired a precise role in the postoperative evaluation of patients after complex surgery, such as, after repair of tetralogy of Fallot, univentricular type of circulation, and in the presence of abnormal blood flow dynamics.

The clinical indications for cardiac MRI are rapidly evolving due to recent considerable technical advances and potential benefits. In 2004, MRI clinical indications were published by a consensus panel composed of European and American cardiologists and radiologists with major input from members with additional established expertise in pediatric cardiology, nuclear cardiology, magnetic resonance physics and spectroscopy, as well as health economics (Table 3.0.2). Interestingly, cardiac MRI expertise is highly recommended in centers dedicated to the treatment of congenital heart defects. Moreover evaluation and follow-up of adults with congenital heart disease is considered as a Class I indication for a comprehensive cardiac MRI investigation, since it is now possible to often answer anatomic and functional questions unresolved with other noninvasive investigations.

Cardiac MRI techniques are generally more operator dependent than other MRI techniques; however, some points should be highlighted: for a reliable study, a thorough understanding of the anatomic and functional principles, as well as the knowledge of the available interventional and surgical therapeutic options for congenital heart defects is nevertheless required. A comprehensive pathophysiological cardiac MRI evaluation, especially if dealing with complex congenital heart defects, requires a long time and may not be well tolerated by the patient. Therefore, accurate and detailed preparatory steps are required in planning the cardiac MRI investigation to precisely define the specific questions to be answered as some lesions may have already been well characterized by other diagnostic modalities. Hence the complete knowledge of all the details of the anatomic and functional findings derived from prior clinical, echocardiography or cardiac catheterization and angiographic studies, as well extensive communication with the referring physician are essential. Frequently, a direct review of previous echocardiography investigation is warranted to check some details of the myocardial function such as ventricular stroke volume in case of atrioventricular valve regurgitation. When dealing with patients with previous interventional and/or surgical procedures, direct access to the previous reports is extremely helpful, as well as the knowledge of the presence of implanted devices as potential sources of artifacts. Furthermore, excellent knowledge of the MRI techniques and physics is warranted to reach high accuracy both in terms of anatomical detail and, more importantly, functional information, often heavily determinant in view of the surgical indication. Thus, every cardiac MRI laboratory should strictly test their own interobserver reproducibility as well as a rigorous quality control of instruments.
To discuss the MRI technique is not the main aim of this chapter, however, we will give an overview on cardiac MRI methodology and technical aspects in order to make the readers more familiar with the technique.

The goals of a pre-operative cardiac MRI investigation in patients with congenital heart defects are the following:

- define the morphological characteristics and the location of the primary malformation and the potential presence of associated defects,
- evaluate and quantify the functional consequences of the primary malformation.

**Morphological assessment:** Although there are several cardiac pulse sequences for MRI morphologic imaging, many with manufacturer-specific features, they can be grouped into three classes:

- **Black-blood imaging:** black-blood images are images with high signal-to-noise ratio, resolution and contrast. Most techniques use radiofrequency refocusing, making them robust to metal artifacts. This is important in the evaluation of postoperative patients where surgical clips would other-

wise cause local image voids and anatomic disruption. Black-blood techniques become very useful when the relationships between the airway and vessels must be elucidated. They are also extremely useful in characterizing the abdominal situs, the presence of masses, thrombi, hematomas or other soft tissue details as fatty infiltration as well as edema.

**White-blood cine imaging:** static pictures as black blood images can answer many questions in pediatric cardiology, but they incompletely characterize the details of the malformation. Any sonographer can relate to the difficulty of interpreting still-frames removed from their dynamic context. Although cine images in MRI can be prospective and retrospectively-gated (not real time), they offer the same physiologic context provided by echocardiography. In most instances the required spatial and temporal resolution makes it impossible to acquire a full series of images in a single heart beat. Instead, each image is assembled from data acquired during several heart beats (segmentation). Cine images represent the backbone of congenital cardiac MRI even though they have lower resolution and contrast than black-blood imaging. In recent years, steady-state free precession (sequences also known as balanced FFE, TrueFisp, and FIESTA) has practically replaced previously used spoiled gradient sequences. The steady-state free precession is extremely useful for imaging of the cardiac function because of its specific properties. Strong T2/T1-weighted and homogeneous contrast shows cavitary blood bright and myocardium with lower signal intensity. Contrast is virtually independent of inflow, imaging at consistent quality in all orientations, including horizontal and vertical long axes. The steady-state free precession sequences are also fast, allowing acquisition of a single slice heart phases in a breath-hold of a few seconds duration.

However, some disadvantages of the steady-state free precession have to be mentioned: the ultra-short TE produces lower flow sensitivity for vascular or valvular obstructions. Even more important steady-state free precession is troubled by flow artifacts near regions of rapid blood acceleration. These artifacts can be even more crippling in infants and young children since they have significantly greater blood acceleration than adult patients in the aorta and the great arteries. Local shimming improves but does not eliminate these artifacts. Another limit of steady-state free precession is that reducing the field of view and slice thickness can greatly prolong the echo and repetition times (this is done to reduce the absorbed radiofrequency power and gradient switching rates).

**3D gadolinium-enhanced angiography:** contrast-enhanced magnetic resonance angiography (CEMRA) is the most important 3-dimensional technique available for routine cardiac assessment. Since voxels are more isotropic than for 2-dimensional acquisitions, images collected by 3-dimensional sequences are ideally suited for multiplanar reformatting and volume rendering. CEMRA acquisitions are un-gated, so they are only useful for characterization of extracardiac structures. Despite short acquisition times, CEMRA has a high signal-to-noise ratio, allowing the highest resolution of any of the cardiac imaging sequences. Although large vessel disease may be well characterized by standard 2-dimensional imaging, CEMRA is absolutely essential to visualize small vessels such as in peripheral pulmonary stenosis or the presence of aortopulmonary collateral arteries. In fact, CEMRA offers comparable diagnostic accuracy as cardiac catheterization and angiography in evaluating the number and location of aortopulmonary collaterals in children and adults with pulmonary atresia.

**Functional assessment:** MRI provides unique functional information of major value related to ventricular function, flow as-
essment, myocardial perfusion and viability. Information on function and flow is obtained from time-resolved series of gradient echo images (white blood), each time frame corresponding to a phase of the cardiac cycle.

**Biventricular function:** one of the advantages of MRI over echocardiography in the assessment of ventricular volumes, ejection fraction and mass is its ability to reproducibly and accurately acquire parallel images in any orientation, eliminating geometrical assumptions. This advantage is especially important in congenital heart disease where the intracardiac morphology does not fit the usual shape assumptions. One example is the unique ability of cardiac MRI to determine ventricular function in patients with a single ventricle, either of right or left ventricular morphology. A single ventricle has an extremely variable and bizarre shape, difficult to mathematically model and which does not allow the geometric assumptions necessary to calculate mass, volume, or cardiac performance from a single image plane. Compared with other noninvasive imaging tools, cardiac MRI provides a precise assessment of the ventricular mass, volumes and function necessary for the early and late postoperative follow-up in these complex patients. The use of MRI has also been extensively validated for the quantification of the right ventricular function.

For measurement of ventricular volumes, a number of adjacent slices are acquired in the short-axis orientation covering them from apex to base. For each short-axis slice, a region of interest is defined by outlining the endocardial contour of the left or right ventricle on the end-systolic and end-diastolic images. For each slice, the area of the region of interest is multiplied by the slice thickness. Summation over all slices results in end-systolic and end-diastolic volume, respectively. The difference between the two volumes corresponds to the stroke volume. From these numbers the ejection fraction is calculated as ejection fraction = stroke volume/end-diastolic volume. Cardiac index is calculated as cardiac output per minute, normalized by the body surface area.

**Velocity mapping:** quantification of blood flow is made using velocity-encoded cine MRI sequence, also called phase contrast velocity mapping (PVC-MRI), through planes transecting the targeted vessel (Fig. 3.0.4), which can provide information on blood flow in the major vessels, such as...
aorta, pulmonary arteries, central veins, and surgically implanted conduits. It represents a unique and unrivaled strength of MRI. The main clinical applications of PVC-MRI, very useful in the assessment of congenital heart defects before and after surgery, are the assessment of the systemic and pulmonary blood flow, the pulmonary to systemic flow ratio (QP/QS) (Fig. 3.0.5), valvular regurgitation, peak velocity measurement in stenotic vessels and valves, lung perfusion and flow dynamics. However, even when appropriate methods of acquisition have been used, there can be inaccuracies of flow measurement caused by background phase errors due to eddy current or uncorrected concomitant gradients. Furthermore for accurate measurements of aortic regurgitation or mitral valve inflow, motion tracking and velocity correction with respect to the cyclic displacements of the valves are needed, but few if any commercial systems provide this facility. Regarding the jet velocity, its measurement poses different challenges, mainly related to the voxel size and slice orientation relative to respectively a narrow jet and jet orientation. A recent application of MRI is to study the compliance of the wall of the great arteries (aorta and pulmonary artery) subjected to a chronic increase of the intravascular blood pressure.

Myocardial tagging: myocardial tagging allows a more thorough investigation of the cardiac motion, providing detailed information on translation, rotation, and deformation, and allows calculation of measures, such as wall motion, regional wall thickening, and strain. This is obtained by destroying coherent magnetization periodically over space and subsequently performing a cine acquisition using a gradient echo sequence. Among other research applications, myocardial tagging has been used to investigate function in children and adult patients with single left ventricle and after heart transplant.

Myocardial perfusion and viability: in adults with coronary artery disease contrast-enhanced MRI allows the identification of myocardial perfusion, extent and diffusion of myocardial ischemia, infarction, and viability. In patients with complex congenital heart disease, myocardial ischemia and fibrosis can also complicate the early and particularly the late follow-up after intracardiac surgery.

First pass perfusion: the currently available MRI perfusion measurement techniques are all based on the dynamic imaging of the first-pass through the myocardium of gadolinium-based T1-shortening contrast agents. Adenosine is used as a coronary vasodilator to create a blood flow difference between the myocardial regions perfused by normal coronary arteries and those supplied by arteries with stenosis. As the contrast agent passes through the blood pool and myocardial tissue, the T1 is shortened, and the signal enhanced. Generally, 20 to 30 seconds are required for the first-pass of contrast agent through the myocardium from the time of injection. This time defines the length of the scan as images must be acquired throughout the passage of contrast agent through the myocardium. Ischemic regions with poor perfusion will not enhance at the same rate as normally perfused tissue and can be visualized as regions of transient dark signal.
Preliminary results demonstrate that MRI evaluation of myocardial perfusion and viability is feasible in pediatric patients with congenital and acquired heart disease, although so far there is a limited application of MRI perfusion imaging in the pediatric population. Cardiac MRI presents advantages in comparison with nuclear scintigraphy, including the lack of ionizing radiation, a very important factor when considering stress imaging in young patients who may require lifelong assessment of myocardial ischemia and function. In comparison with nuclear perfusion examination, which may require 2 to 6 hours, the cardiac MRI examination is generally completed in less than 1 hour. In addition the high spatial resolution of MRI is particularly helpful in pediatric patients because it allows even smaller perfusion defects to be detected. One all-inclusive study also provides complementary data, such as regional wall motion abnormalities and delayed enhancement to evaluate viability. The diagnostic utility and clinical benefit in the pediatric population with congenital and acquired heart disease will be further addressed by future studies.

Delayed myocardial enhancement: gadolinium-based MRI contrast agents in clinical use are all T1-shortening, extravascular, extracellular agents, rapidly diffusing out of the capillaries into the interstitial space. In adult patients, the areas of acute or chronic myocardial infarction provide a larger distribution volume for these agents when compared to viable tissue. T1-weighted, inversion recovery imaging can differentiate necrotic regions of delayed-enhancement from viable myocardium. The inversion time is set to null the signal from viable myocardium, to produce images in which necrotic tissue is bright by virtue of its shorter T1. In practice, the optimal T1 is based on the dose of contrast administered and the elapsed time between injection and imaging. The assessment of the transmural extent of viability by cardiac MRI is not available from other noninvasive imaging techniques. In adult patients with coronary artery disease, the late gadolinium-enhanced cardiac MRI is able to predict whether regions of abnormal ventricular contraction will improve after myocardial revascularization. At the moment, there is only limited experience with this technique in children, even if in infants with an anomalous left coronary artery from the pulmonary artery syndrome and severe left ventricular dysfunction, the impact of myocardial viability, utilizing delayed enhancement to detect ventricular infarct and myocardial fibrosis, has already been reported to direct the surgical choice between the two options of coronary artery reimplantation versus cardiac transplantation.

This technique of post-gadolinium myocardial-delayed enhancement is increasingly used in patients after repair of congenital heart defects to assess the presence and extent of area with myocardial fibrosis.

Sedation and anesthesia

A comprehensive cardiac MRI investigation requires approximately 30 to 60 minutes with the patient in a still position in an uncomfortable environment; therefore, children under the age of 12 will commonly require anesthesia. The use of conscious sedation (such as pentobarbital or chloral hydrate), deep sedation (propofol), or general anesthesia varies tremendously among different hospitals depending upon local preferences and resources. Although general anesthesia with intubation and paralysis is frequently seen as excessively invasive, it is probably safer and more predictable than other strategies in young children. However it becomes highly preferable in patients with vulnerable airways or in infants.
Fig. 3.0.6. Cardiac MRI. Axial time of flight images (a, b, and c) at different levels of the thorax in a patient after an extracardiac Fontan procedure. Arrows indicate the corresponding level to the volume rendering reconstruction (d) showing an unexpected narrowing of the extracardiac conduit between inferior vena cava and pulmonary artery (asterisk). Acquisition parameters were set as follows: flip angle 30°, trigger delay 400 ms; FOV 35×35 cm, fold over direction right-left in order to minimize respiratory artifacts, matrix: 256×160; slice thickness 3 mm; interpolated at 1.5 mm; NEX 2; TE 2.4 ms; TR 6.9 ms (IVC inferior vena cava, PA pulmonary artery, RPA right pulmonary artery, SVC superior vena cava)
Appendix: Cardiac MRI protocols for the evaluation of congenital heart defects

Because the magnet performance changes depending on technical characteristics, manufacturer and type of release, it is worth mentioning that the cardiac protocols discussed in the present book were developed in the MRI laboratory of CNR (Massa-Pisa, Italy) equipped with a GE CVi HD 1.5 T, release software 12.0, coil elements 8 RF channels, slew rate 150 T/m/s, gradient field strength 50 mT/m. Each cardiac MRI investigation starts with a 3-plane localizer. This is a non-gating, free-breathing, white blood, fast acquisition in order to obtain a “pilot” representation of the heart and the mediastinum in three orthogonal planes. Furthermore, in nearly all protocols a 2-dimensional axial “time of flight” acquisition prepared with a stack of thin (3 mm) axial intersected slices, covering the complete thorax from the aortic arch to the diaphragm, is prescribed. It is a quite long lasting, ECG-gated, free-breathing sequence, very useful for further sequences prescription, especially in the case of unusual heart anatomy, thanks to its possibility to be post-processed and reformatted in each plane of the space. Moreover, thanks to its high resolution and optimal visualization of mediastinal vessels, it can be used as an alternative to MR angiography without using contrast medium and any venous line (Fig. 3.0.6), a non-negligible advantage in children. After the heart and great vessels have been “localized”, in nearly each cardiac MRI investigation, a series of cine acquisition from the axial view (Fig. 3.0.7). Cardiac MRI. Steps to obtain the correct inclination for imaging in the cardiac axes: from a transverse or axial scout view at the level of the left ventricle (a), proceeding as shown, a 2-chamber view is obtained (b); from b is obtained a “localized short axis” (c). From the last two images (2-chamber and “localized short axis”) a 4-chamber view (d) is obtained. A true short-axis plane stack can now be prescribed off the 4-chamber view perpendicular to the interventricular septum. The short-axis stack should cover the entirety of both ventricles from the atrioventricular valves to the apex.

Definition

An anomalous systemic venous connection is present in 8 to 10% of patients with congenital heart defects. The most frequent congenital anomaly of systemic venous return is the presence of a persistent left superior vena cava (Figs. 3.1.1 and 3.1.2), in most of the cases connected to the coronary sinus, but sometimes draining into the left atrium. The persistent left superior vena cava can be associated with the absence of the right superior vena cava (Fig. 3.1.3). The strategy of cardiopulmonary bypass can be completely different if the persistent left superior vena cava is associated with the presence or the absence of the innominate vein and/or right superior vena cava.

Fig. 3.1.1. Persistent left superior vena cava. a CT scan, coronal view, showing the presence of persistent left superior vena cava draining into the coronary sinus, with absent innominate vein. b CT scan of the same patient, coronal view, showing the drainage into the coronary sinus of the persistent left superior vena cava (CS coronary sinus, LA left atrium, PLSVC persistent left superior vena cava, RA right atrium, SVC superior vena cava) (photographs courtesy of Dr. Mohamed Tawil)

Fig. 3.1.2. Persistent left superior vena cava. MR angiography maximal intensity projection reconstruction in a patient with aortic coarctation and persistent left superior vena cava draining into a dilated coronary sinus and not communicated with the right superior vena cava (Asc Ao ascending aorta, Coa aortic coarctation, CS coronary sinus, SVC superior vena cava)
Another anomaly of the systemic venous return is the interruption of the inferior vena cava (Figs. 3.1.4 and 3.1.5) with the drainage of the inferior part of the body occurring through an “azygos continuation”. If an open heart procedure is required, the presence of one or more of the above malformations will dictate not only the number and position of the venous cannulae, but also the strategy of cardiopulmonary bypass (continuous perfusion versus circulatory arrest).

Other more rare anomalous systemic venous connections (Figs. 3.1.6 and 3.1.7) must be taken into account before planning the surgical strategy.

**Fig. 3.1.3.** Persistent left superior vena cava with absent right superior vena cava. Gadolinium-enhanced 3-dimensional MR angiography with subvolume maximal intensity projection in the coronal plane demonstrating the absence of the right superior vena cava and persistent left superior vena cava draining in a dilated coronary sinus (RA right atrium, RPA right pulmonary artery, SVC superior vena cava)

**Fig. 3.1.4.** Inferior vena cava interruption with azygos continuation. CT scan, sagittal projection, showing the azygos continuation of the inferior vena cava and the connection of the azygos vein to the superior vena cava (arrow) (AV azygos vein, IVC inferior vena cava, LV left ventricle, RV right ventricle, SVC superior vena cava) (photograph courtesy of Dr. Mohamed Tawil)

**Fig. 3.1.5.** Inferior vena cava interruption with azygos continuation. MRI with coronal localizer showing inferior vena cava azygos continuation in the left superior vena cava (RA right atrium, SVC superior vena cava)

**Surgical options**

Once the problems related to the requirements of the cardiopulmonary bypass have been solved, with the choice of the most appropriate venous cannulation and the method of perfusion, the anomalous systemic venous connection has to be addressed.

**Persistent left superior vena cava:** The persistent left superior vena cava draining into the coronary sinus is generally left intact, unless the patient requires a superior vena cava to pulmonary artery connection (= bidirectional Glenn), and the innominate vein is absent; in this case, a bilateral bidirectional Glenn is performed. On the other hand, the presence of persistent left superior vena cava draining into the left atrium, with subsequent cyanosis, is different. In this case, the superior vena cava needs to be disconnected from the left atrium. There are two options: a) in the simultaneous presence of innominate vein of adequate diameter, simple ligation of the persistent superior vena cava is sufficient; b) in the absence of innominate vein, the distal end of the persistent left superior vena cava needs to be divided and the vein connected either directly to the right auricular appendage or to the right superior vena cava.

**Interruption of the inferior vena cava:** The interruption of the inferior vena cava is im-
important whenever the patient requires a total cavopulmonary connection (= modified Fontan procedure). In these cases, the best surgical option is to perform a Kawashima procedure: connecting the superior vena cava (draining the total systemic venous return through the “azygos continuation”) to the right pulmonary artery, like in the bidirectional Glenn, leaving the return of the hepatic vein into the right (or left) atrium (see chapter “Tricuspid atresia”).

Pre-operative information

Echocardiography is generally limited in the evaluation of systemic venous return, while both CT and MRI 3-dimensional volume-rendered images give important insights for the assessment and location of anomalous systemic venous connections; CT and MRI allow also detection of systemic veins relationship to the surroundings structures and can evaluate potential associated congenital heart defects.

MRI can accurately evaluate systemic venous connections by gradient and spin echo and more recently by contrast-enhanced MR angiography. For the MRI assessment of the systemic venous connections a 2-dimensional axial Time of Flight (TOF) sequence prescribed from the neck to the liver (see “Introduction chapter”) without using contrast agent provides a complete coverage of the thoracic systemic veins.

Obviously the entire CT or MRI investigations will be tailored to the potential presence of associated congenital heart disease.

Potential complications

Obstruction or total occlusion of the anomalous systemic venous connection.

Post-operative follow-up

CT scan and MRI could be helpful to identify or rule out potential obstructions or occlusions (Fig. 3.1.8) of the systemic venous connections after various procedures of cardiac surgery.

Partial anomalous pulmonary venous connection: One or more, but not all, of the pulmonary veins are connected to the right atrium or to one or more of its tributaries.

The commonest type of partial anomalous pulmonary venous connection is the sinus venosus defect: the right upper and middle lobe pulmonary veins (right superior pulmonary vein) attach to the low superior vena cava or the superior vena cava-right atrium junction (Figs. 3.2.1–3.2.3).

Anomalous left-sided pulmonary veins usually connect to the coronary sinus or left innominate vein (Fig. 3.2.4), while anomalous right pulmonary veins usually connect to the superior vena cava, inferior vena cava or right atrium.

Scimitar syndrome: all the right pulmonary veins (occasionally the middle and lower pulmonary veins) are connected to the inferior vena cava just above or below the diaphragm (Fig. 3.2.5); the orifice of the right pulmonary veins is usually very close to the orifices of the hepatic veins. Scimitar syndrome can also be associated with horseshoe lung (Fig. 3.2.6).

The left innominate vein is the usual site of anomalous connection of the left pulmonary veins via a derivative of the left cardinal system, called the anomalous vertical vein.

Bilateral partial anomalous pulmonary venous connection (= partial anomalous venous connection of both lungs) is very rare: the commonest variant is probably that in which the left superior pulmonary vein attaches to the left innominate vein by way of an anomalous vertical vein, and the right superior pulmonary vein attaches to the superior vena cava-right atrial junction.

Total anomalous pulmonary venous connection: All the pulmonary veins connect anomalously to the right atrium, either directly or via the coronary sinus, superior vena cava, or inferior vena cava; a patent foramen ovale or atrial septal defect allows
mixed blood in the right atrium to enter the left heart for systemic distribution; usually the confluence of the pulmonary veins is posterior to the left atrium, but separate from it.

There are four basic types:
- **supracardiac**: the anomalous connection is to an ascending vertical vein, usually on the left and connected to the left innominate vein; pulmonary venous obstruction is possible,
- **cardiac**: the pulmonary veins connect directly to the right atrium or (more frequently) to the coronary sinus; pulmonary venous obstruction is rare,
- **infracardiac**: (or infradiaphragmatic) the connection is to intraabdominal veins (more frequently to the portal vein); pulmonary venous obstruction is very frequent,
- **mixed**: the entire pulmonary venous drainage is through two (or more) of the above connections.

### Surgical options

**Partial anomalous pulmonary venous connection:**

**Anomalous right pulmonary vein(s) connected to the superior vena cava**

The right atrial incision depends on the position of the anomalous pulmonary vein(s).

**Standard oblique atriotomy**: the upper right pulmonary vein is deviated to the left atrium by means of a patch (synthetic or pericardial) sewn along the wall of the superior caval vein so as to include the anomalously connected vein(s); suturing of the patch is then carried down into the right atrium, and then sewn around an unrestricted interatrial communication (already present or surgically created) in the upper part of the interatrial septum. In this way, the anomalously connected right pulmonary vein(s) can drain through a tunnel, whose posterior wall is composed of the superior caval vein and whose anterior wall is composed of a patch through the atrial septal defect into the left atrium.

**Posterior incision**: another surgical option is the posterior incision of the right atrium, prolonged on the superior vena cava; this approach allows the plastic procedure of en-
larging the superior vena cava by a synthetic or pericardial gusset placed in the superior vena cava-right atrial junction.

**Anomalous right pulmonary vein(s) connected to the inferior vena cava**

Two surgical options are available: tunneling the anomalous right pulmonary vein(s) to the left atrium trough an atrial septal defect (like for the anomalous connection to the superior vena cava), or disconnection of the anomalous venous channel from the inferior vena cava and direct anastomosis to the left atrium.

**Anomalous left pulmonary vein(s)**

Different techniques have been reported to repair the anomalous left pulmonary vein(s), all use an end-to-side or side-to-side anastomosis between the left pulmonary vein(s) and the left auricular appendage.

**Scimitar syndrome:** correction of the scimitar syndrome may be technically demanding due to the infradiaphragmatic portion of the anomalous venous connection. Exposure of this portion of the vein is afforded by splitting the diaphragm to the veno-caval hiatus. In some patients, the repair may only require removal of the inferior vena cava cannula to expose the anomalous venous ostium during a brief period of deep hypothermic circulatory arrest. In this instance, an intraatrial baffle is used in much the same way as a partial anomalous venous connection with a sinus venosus defect. A final alternative technique consists of extracardiac reimplantation of the scimitar vein into the posterior wall of the right atrium followed by transposition of the atrial septum anterior to the new ostium, either directly or with a patch.

**Total anomalous pulmonary venous connection:**

**Supracardiac and infracardiac type:** a large anastomosis is created between the anterior wall of the common pulmonary venous sinus and the posterior wall of the left atrium, both opened wide to obtain an unrestrictive connection;

- the approach can be biatrial (right atriotomy, opening of the interatrial septum), posterior or superior (between aorta, right pulmonary artery and the roof of the left atrium),

---

**Fig. 3.2.3.** Partial right anomalous pulmonary venous connection with sinus venous atrial septal defect. Cardiac MR angiography with para-coronal (a) and axial (b) reformatted time of flight showing a sinus venous atrial septal defect (green arrow) with anomalous right upper pulmonary vein connected to the superior vena cava-right atrial junction. Note a small additional right upper pulmonary vein connected more distally to the superior vena cava (blue arrow) (LA left atrium, LLPV lower left pulmonary vein, LRPV lower right pulmonary vein, RA right atrium, RUPV right upper pulmonary vein, SVC superior vena cava)
the ascending (or descending) vertical vein may be left open (to allow heart decompression), or ligated, or transected and opened longitudinally to be utilized to create a wider anastomosis,
- the patent foramen ovale may be closed or left (partially) open to allow heart decompression,
- the left atrium may be enlarged with a single or double patch technique to improve left ventricular filling.

**Cardiac type:** the total pulmonary venous return is deviated to the left atrium through an unrestricted (or surgically enlarged) interatrial communication by a patch; in the case of coronary sinus type, the roof of the coronary sinus in incised (or excised) to create an unrestricted connection.

**Mixed type:** surgical treatment must be individualized and based on the particular morphology.

**Pre-operative information**

**Partial anomalous pulmonary venous connection:** If a clinical doubt in the presence of partial anomalous venous connection cannot be solved with confidence by echocardiography, CT scan and MRI are the most appropriate additional diagnostic imaging tests. The acoustic properties of lung tissue makes it difficult using echocardiography to trace potential anomalous veins back into the lungs to confirm that they are pulmonary rather than systemic veins. This limitation is not encountered with CT scan and MRI.

The goals of CT scan MRI evaluation of partial anomalous pulmonary venous connection include precise delineation of the anatomy with location, size and connection site of the anomalous vein(s) by means of CT angiography with contrast material as well as gadolinium-enhanced 3-dimensional MR angiography (Figs. 3.2.1–3.2.5). The image dataset can be reformatted into any plane to illustrate spatial relationships and has sufficient resolution to detect vessels <1 mm. For added confidence, additional MRI imaging of the vascular anatomy can be obtained using cine gradient echo or fast spin echo with blood signal nulling sequences (Fig. 3.2.2). Several studies assessing the accuracy and utility of gadolinium-enhanced 3-dimensional MRI have demonstrated a high level of agreement between findings on MR angiography compared with surgical inspection and X-ray angiography. MR angiography were uniformly more accu-
rate than transthoracic and transesophageal echocardiography. MRI investigations often diagnosed previously unknown presence of a partial anomalous pulmonary venous connection or added new clinically important information regarding anatomical details of the partial anomalous pulmonary venous connection.

Patients with a partial anomalous pulmonary venous connection should also have their ventricular dimensions and function measured using a stack of cine MRI oriented in the ventricular short-axis plane. Particular attention should be devoted to quantifying right ventricular end-diastolic volume as this should be related to the size of the left-to-right shunt. The shunt should also be measured directly by obtaining PVC MRI flow measurements in the main pulmonary artery (QP) and the ascending aorta (QS) (Fig. 3.2.4). It is worth noting that, in patients with partial anomalous pulmonary venous connection, QP/QS ratio measurements by oxymetric measurements in the catheterization laboratory are inherently inaccurate because of the difficulty in obtaining a reliable, representative mixed systemic venous saturation. Because blood flow is measured directly, these concerns do not apply to MRI measurements. In cases where there is a hypoplastic pulmonary artery or obstruction to the pulmonary venous return, it is also useful to calculate differential pulmonary blood flow by means of MRI measurements in the branch pulmonary arteries (Fig. 3.2.6 a).

In the presence of scimitar syndrome, the pre-operative CT scan and MRI, in addition to the visualization of the anomalous venous connection, are also useful to evaluate the degree of hypoplasia of the right lung, pulmonary artery and other associated anomalies (Figs. 3.2.5 and 3.2.6).

In case of a suspected anomalous pulmonary venous connection a comprehensive cardiovascular MRI investigation considers the following protocol:
3-plane localizing images,
2-dimensional axial Time-of-flight Angiography mainly to evaluate the pulmonary veins (see chapter 3.0) (Fig. 3.2.3),
oblique axial and para-sagittal fast spin echo and segmented k-space cine steady-state free precession pulse sequences at the atrial level for anatomical detail of the atrial septal defect and the pulmonary veins connections and their relationship (Fig. 3.2.2),
ECG-gated cine steady-state free precession sequences for quantitative assessment of both ventricular dimensions and function, and stroke volumes.
ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending aorta, pulmonary branches and pulmonary veins, to assess the QP/QS, the pulmonary arteries blood flow and pulmonary veins blood flow when needed,
gadolinium-enhanced 3-dimensional MR angiography for the evaluation of pulmonary venous return (Figs. 3.2.2, 3.2.4 and 3.2.6).

Fig. 3.2.6. Scimitar syndrome associated with horseshoe lung. (a) Gadolinium-enhanced 3-dimensional MR angiography maximal intensity projection of the pulmonary branches illustrating the mild hypoplasia and reduced flow of the right pulmonary artery, calculated with PVC. 3-dimensional MR angiography volume rendering reconstruction (b) and maximal intensity projection (c) showing a crossing small right pulmonary artery branch (green arrow) = horseshoe lung (IVC inferior vena cava, LA left atrium, LPA left pulmonary artery, LV left ventricle, PA pulmonary artery, Pulm pulmonary, RA right atrium, RPA right pulmonary artery, RV right ventricle)
Fig. 3.2.7. Obstructed supracardiac total anomalous pulmonary venous connection. CT scan, subvolume maximum intensity coronal projection, showing supracardiac total anomalous pulmonary venous connection with obstruction (arrowheads) of the vertical vein (asterisks) connecting the pulmonary venous conector to the innominate vein (IV innominate vein, LLPV left lower pulmonary vein, LUPV left upper pulmonary vein, MPA main pulmonary artery, PVC pulmonary venous connector, RLPV right lower pulmonary vein, RPA main pulmonary artery, RUPV right upper pulmonary vein, SVC superior vena cava) (modified with permission from Goo HW, Park IS, Ko JK, Kim YH, Seo DM, Yun TJ, Park JJ, Yoon CH (2003) CT of congenital heart disease: normal anatomy and typical pathologic conditions. Radiographics 23:S147–165)

Fig. 3.2.8. Infra-cardiac total anomalous pulmonary venous connection. Gadolinium-enhanced 3-dimensional MR angiography showing unobstructed infracardiac total anomalous pulmonary venous connection. Maximal intensity projection (a, b, c) and 3-dimensional volume rendering reconstruction (d) showing all pulmonary veins connected to the inferior vena cava through an unobstructed pulmonary venous collector (red arrow) (IVC inferior vena cava, LPA left pulmonary artery, PVs pulmonary veins, RA right atrium, RPA right pulmonary artery, SVC superior vena cava)
Total anomalous pulmonary venous connection: Total anomalous pulmonary venous connection is clinically suspected early in life and echocardiography generally provides adequate information on the presence and location of anomalous pulmonary venous connections. However, if any doubt persists, mainly in cases with mixed or complex forms of total anomalous pulmonary venous connection, both 3-dimensional multi-planar volume-rendered CT images and MRI contrast angiography can be extremely useful to delineate the connection of each pulmonary vein (Figs. 3.2.7–3.2.9).

Potential complications

Residual or recurrent intraatrial shunt, air embolism (early), acute pulmonary edema, pulmonary arterial hypertensive crisis, phrenic nerve damage, supraventricular arrhythmias, pulmonary venous obstruction, systemic venous obstruction, anastomotic obstruction, systemic and pulmonary thromboembolism (late).
In the postoperative setting, CT scan and MRI are very useful tools to rule out potential residual defects (Figs. 3.2.10–3.2.13).

MRI is particularly important when the following residual complications are suspected: intraatrial shunts, systemic and/or pulmonary venous obstructions, leak and/or obstruction of the intraatrial baffle.

As for the pre-operative evaluation, in addition to the possibility of assessing the ventricular volumes and quantifying the residual shunts, each pulmonary and systemic vein can be optimally visualized by 3-dimensional MR angiography. Moreover in some cases it is possible to study the anomalous flow pattern of obstructed veins by means of PVC-MRI.
Fig 3.2.13. Status post repair of scimitar syndrome. MRI with gadolinium-enhancement volume rendering oblique plane (a = anterior view, b = posterior view) showing a significant narrowing of the inferior vena cava due to the intraatrial PTFE baffle, as later confirmed at re-operation to relieve the obstruction. The inferior systemic venous return drains principally into the superior vena cava through a dilated azygos and hemiazygos veins as shown from maximal intensity projection (c = posterior view). In a, note that there are some suprahepatic veins draining into the PTFE scimitar-to-left atrium conduit, leading to mild systemic oxygen desaturation. In the volume rendering imaging (d = anterior view) note the “kinking” of the baffle-scimitar anastomosis (IVC inferior vena cava, LA left atrium, RA right atrium, SVC superior vena cava)

phy in the diagnosis of total anomalous pulmonary venous drainage. Circulation 101:2017–2018

To understand the anatomy determining the presence of shunts between the atrial chambers, it is crucial to appreciate the difference between a defect of the atrial septum and an interatrial communication.

**True atrial septal defects**: defects existing within the floor of the fossa ovalis; they can be produced by an insufficient or perforated flap valve; defects within the fossa (so-called “ostium secundum” defects) must be distinguished from probe-patency of the fossa, in which the flap valve overlaps, but does not seal anatomically, the rim.

**Sinus venosus**: interatrial communications in the mouth of usually the superior, but sometimes the inferior, vena cava; they are outside the floor of the fossa ovalis. Their anatomical feature is overriding of the superior or posterior margin by the mouth of the superior or inferior vena cava, respectively.

**Coronary sinus**: defects existing through the mouth of the sinus when there is a wide fenestration between the wall of the sinus and the left atrium. Usually, but not always, the left superior vena cava drains to the roof of the left atrium (see chapter “Unroofed coronary sinus”).

**Ostium primum**: defects between the leading edge of the atrial septum and the upper margin of the ventricular septum. They are atroventricular septal defects and have a common atroventricular junction (see chapter “Atrioventricular septal defects”).

Atrial septal defects within the fossa ovalis may coexist with nearly all varieties of congenital heart disease, but such cases are not considered the primary lesion unless the left-to-right shunt at the atrial level is the dominant hemodynamic lesion. Partial anomalous pulmonary venous connection (virtually always present in patients with sinus venosus defect), mitral valvar prolapse, ventricular septal defect, patent ductus arteriosus, pulmonary valvar stenosis, peripheral pulmonary arterial stenosis, and persistence of the left superior vena cava are the lesions which are more frequently found secondary to interatrial communications.

**Surgical options**

The percutaneous closure with a device implanted using an interventional cardiac procedure is nowadays considered whenever possible.

In all other cases, the defect is surgically approached through a right atriotomy on cardiopulmonary bypass. True atrial septal defects are closed by direct suture or patch closure of the defect (depending on the size and shape of the defect).

Sinus venosus atrial septal defects are treated by patch closure of the defect, leaving the right pulmonary veins on the left side of the patch, with unrestricted communication with the left atrium, and avoiding damage to the sinus node (and the sinus node artery) by the suture line (see chapter “Partial anomalous pulmonary venous connection”).
Pre-operative information

Ostium secundum atrial septal defect is usually sufficiently evaluated, mainly in children, by transthoracic echocardiography for diagnosis and indication to management, even if percutaneous transcatether occlusion of secundum atrial septal defects has increased the need for accurate anatomic information of the defect size, morphology, and spatial relationships.

However, a few recent reports proposed evaluating the ostium secundum atrial septal defect by MRI prior to attempting percutaneous closure to correctly identify those patients not suitable for such a procedure due to anatomical problems. This approach can result in the avoidance of unneeded invasive and radiologic ionizing procedures or transesophageal echocardiography which, although more accurate but semi-invasive, is not well tolerated and needs general anesthesia in children.

The anatomical evaluation of the atrial septum by MRI includes location, size and number of the atrial septal defects by both cine MRI sequences and “black blood” static images performed with breath-holding and ECG-gating (Fig. 3.3.1).

Optimal images are necessary to avoid overestimation of the defect’s size. It has been reported that the spin-echo measurements resulted in significantly larger defect sizes compared with the reference standards, and the discrepancy was attributed to “signal dropout” in the thin portion of the septum. Therefore, in some studies defect size and rim measurements were assessed using velocity encoded cine MRI oriented in the plane of the atrial septum for en face visualization and in orthogonal planes for the distance from adjacent structures.

Fig. 3.3.1. Ostium secundum atrial septal defect. Cine MRI short-axis view of the atrial septum (a), 4-chamber view (b), and “black blood” (fast spin echo) oblique sagittal plan of the atrial septum (c). Note the ostium secundum atrial defect (asterisk) (LA left atrium, RA right atrium, asterisk = defect)
In order to quantify the shunt, a commercially available gradient-echo phase velocity mapping ECG-triggered sequence is used for the blood flow determination at the pulmonary and aortic levels (for calculation of the pulmonary-to-systemic flow ratio = QP/QS). QP/QS can also be derived from the right and left ventricular stroke volumes calculated from the short-axis cine stack of the ventricles, paying close attention to consider the potential presence of atrioventricular valve regurgitation. This image series can also help to obtain a qualitative estimate of right ventricular systolic pressure based on the configuration of the ventricular septum.

Cardiac MRI is particularly indicated in patients with echocardiographic diagnosis of suspected ostium primum atrial septal defect (Fig. 3.3.2) and sinus venous atrial septal defect (Fig. 3.3.3), in order to visualize both the defect and the pulmonary venous return in detail as well as to correctly quantify the left to right shunt and the volume overload imposed to the right heart. Moreover as a first-line diagnostic tool for the evaluation of the pulmonary veins, MRI is particularly useful in patients with right ventricular volume overload in whom transthoracic echocardiography cannot clarify its cause.

In patients with atrial septal defect, a comprehensive cardiovascular MRI investigation considers the following protocol:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography mainly to evaluate the pulmonary veins (see appendix in "Introduction"),
- oblique axial and para-sagittal fast spin echo and segmented k-space cine steady-state free precession pulse sequences at the atria level for anatomical detail of atrial septal defect and pulmonary venous connections and their relationship,
- ECG-gated phase contrast velocity mapping MRI sequence parallel to the atrial septum plane in order to better delineate the size, shape and rims of the defect,
- ECG-gated cine steady-state free precession sequences for quantitative assessment of both ventricular dimensions and functions, and stroke volumes,
- ECG-gated phase contrast velocity mapping MRI sequences perpendicular to the main pulmonary artery, ascending aorta, pulmonary branches, to assess QP/QS,
Gadolinium-enhanced 3-dimensional MR angiography for the evaluation of pulmonary venous return.

Potential complications

Residual or recurrent atrial septal defect, air embolism (early), systemic and pulmonary thromboembolism (late), supraventricular arrhythmias (particularly in adult patients), pericardial effusion (frequent).

Post-operative follow-up

Current MRI techniques are inferior to trans-oesophageal echocardiography for detection of residual left-to-right and through the atrial septum after device closure of interatrial communications.

In patients post transcatheter closure of an atrial septal defect (Fig. 3.3.4), MRI can rule out device malposition, interference with the atriocentric valves and venous blood flow, thrombus formation.

After surgical repair of sinus venous atrial septal defect, cardiac MRI could be helpful to rule out iatrogenic obstruction of the systemic or pulmonary venous return.

Fig. 3.3.4. Post transcatheter closure of ostium secundum atrial septal defect. 4-chamber view cine steady-state free precession MRI showing the good position of the Amplatzer device (asterisk) (LA left atrium, RA right atrium)

References

**Definition**

*Complete form:* the common wall between the coronary sinus and the left atrium (roof of the coronary sinus) is totally absent.

*Partial form:* an opening is present in the mid-portion of the wall between the coronary sinus and the left atrium (also called biatrial opening of coronary sinus or coronary sinus to left atrial fenestration). Associated cardiac anomalies: persistent left superior vena cava (very frequent), atrial septal defect, common atrium, partial or complete atrioventricular septal defect, mitral stenosis, mitral atresia, tricuspid atresia, tetralogy of Fallot, atrial isomerism.

**Surgical options**

Surgical repair can be accomplished with two techniques:

- complete excision of the entire atrial septum except for a rim of the anterior limbus, in order to preserve the conduction system, followed by suture of a pericardial or synthetic patch as a repositioned atrial septum, leaving all three caval vein orifices on the right site of the patch;
- re-routing the coronary sinus to the roof of the left atrium, by using the incised atrial septum, and then reconstructing an atrial septum with a pericardial or synthetic patch.

Alternative surgical techniques consist of transection of the persistent left superior vena cava and its Anastomosis to the right
superior vena cava, to the right auricular appendage, or directly to the left pulmonary artery.

**Pre-operative information**

The anatomy of the coronary sinus and its tributary veins can be evaluated using CT. The most frequent observation (63% of the cases) is the separate insertion of the coronary sinus and the small cardiac vein in the right atrium. The second most frequent appearance (29%) is the continuity of the anterior and posterior venous system at the crux cordis. Less frequent (8%) is the absence of a connection between the posterior interventricular vein and the coronary sinus.

When the presence of persistent left superior vena cava is diagnosed, especially if associated with situs abnormalities, an unroofed coronary sinus always has to be ruled out and this could be a difficult task with echocardiography. In these cases, CT scan (Fig. 3.4.1) and MRI (Fig. 3.4.2) should be considered as the first-line diagnostic tools due to the high resolution images, independent of body size and the location of the targeted structure. A few reports have been published regarding CT and MRI diagnosis of unroofed coronary sinus, generally associated with complex congenital heart disease. However, unroofed coronary sinus is often an intraoperative finding.

---

**Fig. 3.4.2.** Unroofed coronary sinus (reproduced with permission from Hahm JK, Park YM, Lee JK, Choi JY, Sul JH, Lee SK, Cho BK, Choe KO (2000) Magnetic resonance imaging of unroofed coronary sinus: three cases. Pediatr Cardiol 21:382–387)
Potential complications

- Obstruction of the persistent left superior vena cava and/or of the left pulmonary veins, residual or recurrent atrial septal defect, air embolism, supraventricular arrhythmias.

Post-operative follow-up

CT scan (Fig. 3.4.3) and MRI (Fig. 3.4.4) can be useful to visualize the surgical reconstruction with the deviation of the venous return from the persistent left superior vena cava to the right atrium, and to rule out the presence of residual obstructions and/or intracardiac shunts.
References

## Definition

Types of atrioventricular septal defect accordingly with the Anderson classification:

- **Separate atrioventricular orifices, shunting at the atrial level**: ostium primum defect, three leaflet left atrioventricular valve (so-called mitral valve with cleft anterior leaflet).
- **Separate atrioventricular orifices, shunting at the atrial and ventricular levels**: ostium primum defect, space between superior and inferior bridging leaflets of the left atroventricular valve, inlet ventricular septal defect partially or almost completely closed by fibrous tissue of the atroventricular valve.
- **Common atrioventricular orifice, shunting at atrial and ventricular levels**: ostium primum defect, common atrioventricular valve, unrestrictive inlet ventricular septal defect (Fig. 3.5.1).

### Associated anomalies

- Patent ductus arteriosus, tetralogy of Fallot or double outlet right ventricle with ventriculoarterial concordance (more frequent in Down’s syndrome), left ventricular outflow tract obstruction (more frequent in patients with separate atrioventricular orifices and those without Down’s syndrome), unbalanced ventricles (right ventricular dominance more frequent in patients without Down’s syndrome), persistent left superior vena cava with or without unroofed coronary sinus, additional muscular ventricular septal defects, accessory left atrioventricular valve, single papillary muscle in the left ventricle.

## Surgical options

In the presence of a complex anatomical situation, like right or left ventricular dominance, or associated cardiac malformations (e.g., aortic coarctation or aortic arch interruption) or in patients very ill because of repeated infections and/or associated noncardiac malformations, the palliative approach with pulmonary artery banding can be considered as an alternative. Pulmonary artery banding can be accomplished with the conventional technique of implanting a tape around the main pulmonary artery or with a telemetrically adjustable device (FloWatch®, EndoArt, Lausanne, Switzerland).

In all cases the surgical approach for repair is from a right atriotomy. In the case of the double patch technique, a prosthetic patch (PTFE, Dacron, Teflon) is used for the ventricular component and a biological patch (autologous or heterologous pericardium) for the atrial component. In the case of the single patch technique, either a prosthetic or biological patch is used according to the surgical preferences.

- **Separate atrioventricular orifices, shunting at the atrial level**: patch closure of ostium primum ± suture of the space between the bridging leaflets (“cleft”).
- **Separate atrioventricular orifices, shunting at atrial and ventricular levels**: as above with patch closure of the ventricular septal defect.
Common atrioventricular orifice, shunting at atrial and ventricular levels:

- Single patch closure of atrial and ventricular septal defects, division of the bridging leaflets and resuspension to the patch, with or without suture of the so-called “cleft”
- Double patch closure of atrial and ventricular septal defects, bridging leaflets “sandwiched” between atrial and ventricular patches, with or without suture of the so-called “cleft”.

In both techniques: test the competence of the left atrioventricular valve with injection of saline solution under pressure in the left ventricle; in case of significant regurgitation, adjust the repair by shifting the valvular leaflets with additional sutures; caution should be used to avoid creating left atrioventricular valvular stenosis or subvalvular aortic stenosis.

Pre-operative information

Pre-operative echocardiographic evaluation of patients with atrioventricular septal defect generally provides enough information for the decision-making process without the requirement for other investigations, unless associated cardiac malformations or the presence of elevated pulmonary vascular resistance are suspected.

Cardiac MRI could be useful in case of isomerism, not rare in such patients, in order to delineate systemic and pulmonary venous connections, and whenever more anatomical details are requested, such as in other congenital heart defects. The goal of MRI, therefore, is to visualize the systemic and pulmonary venous connections, quantify the ventricular volumes and functions particularly in unbalanced ventricular chambers, visualize the left ventricular outflow tract, and determine the precise relationship between the ventricular septal defect and the ventricular outflow tract.

To achieve these goals we propose the following cardiac MRI protocol:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix in the “Introduction”),
- ECG-gated cine steady-state free precession sequences in the 2-chamber and 4-chamber planes, and ventricular short axis for the quantitative assessment of both the ventricular dimensions, function and stroke volume (Fig. 3.5.2), as illustrated in the appendix of the “Introduction”,
- ECG-gated cine steady-state free precession and static fast spin echo sequences on additional planes are often required to better determine the anatomy of the os- tum primum defect (Figs. 3.5.2 and 3.5.3), the location of the coronary sinus, the anatomy of the ventricular septal defect (Fig. 3.5.4) and its relationship with the great arteries,
- ECG-gated cine steady-state free precession double-oblique sequences on two perpendicular planes to visualize the left ventricular outflow tract (Fig. 3.5.2),
Fig. 3.5.2. Atrioventricular septal defect with common atrioventricular orifice and hypoplastic left ventricle. MRI cine steady-state free precession 4-chamber view (a) and ventricular short-axis view (b) showing the ostium primum defect (asterisk) and the presence of hypoplastic left ventricle; cine steady-state free precession double-oblique sequences of left ventricular outflow tract showing the typical goose-neck appearance of the left ventricular outflow tract (c) (Ao aorta, LA left atrium, LV left ventricle, RA right atrium, RV right ventricle).
ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery and ascending aorta to calculate the QP/QS.

Gadolinium-enhanced 3-dimensional MRA for the evaluation of pulmonary and systemic venous connections if required.

Potential complications

Residual or recurrent atrial and/or ventricular septal defect, complete atrioventricular block, left atrioventricular valvar regurgitation and/or stenosis, left ventricular outflow tract obstruction, pulmonary arterial hypertensive crisis.

Post-operative follow-up

Post-operative echocardiography after repair of atrioventricular septal defect generally provides all the required information on the adequacy of the surgical procedure.

MRI could be useful in the presence of residual intracardiac defect to quantitate the residual intracardiac shunt, to evaluate resid-
ual atrioventricular valve regurgitation (Fig. 3.5.5), to visualize the left ventricular outflow tract and to quantify the ventricular volumes and functions particularly in unbalanced ventricular chambers.

**References**

**Definition**

- **Perimembranous ventricular septal defect:** the membranous septum is very small, therefore, ventricular septal defects usually extend into the surrounding muscle septum, and this is called perimembranous ventricular septal defect; this type of ventricular septal defect is the most common after infancy, accounting for 75% of all ventricular septal defects; defect surrounding the membranous septum, at the meeting point of the three right ventricular components (inlet, apical trabecular and outlet); the diagnostic feature is fibrous continuity between the leaflets of the aortic and tricuspid valves; can extend to open mostly to the inlet or outlet of the right ventricle, or can be confluent,

  - **juxta-crus ventricular septal defect:** particular posterior perimembranous defect associated with straddling and overriding of the tricuspid valve; diagnostic feature is malalignment between the atrial and ventricular septum.

- **Muscular ventricular septal defect:** this is the second most common type of ventricular septal defect after infancy; in infancy, muscular ventricular septal defect is the most frequent type, but most of them, very small in size, undergo complete spontaneous closure; a defect, which has completely muscular rims, can be situated anywhere within the septum, but can be subdivided into those opening to the inlet, trabecular or outlet components of the right ventricle.

- **Doubly committed juxtaarterial ventricular septal defect:** defect limited superiorly by fibrous continuity between the leaflets of the pulmonary and aortic valves, because of absence of the outlet septum and the septal component of the subpulmonary infundibulum; can have a muscular posterior rim or can extend to become perimembranous.

- **Multiple ventricular septal defects:** combination of multiple muscular defects or of one or more muscular defect(s) co-existing with perimembranous or juxtaarterial defects.

- **Inlet ventricular septal defects:** (see chapter “Atrioventricular septal defects”)

A ventricular septal defect may coexist with nearly all varieties of congenital heart disease, but the interventricular communication is only considered the primary lesion when the left-to-right shunt at the ventricular level is the dominant hemodynamic lesion.

Atrial septal defect, partial (or total) anomalous pulmonary venous connection, infundibular or pulmonary valvular stenosis, double-chambered right ventricle, mitral stenosis, discrete (fibrous) subvalvar aortic stenosis, aortic valvular regurgitation (Laubry-Pezzi syndrome), aneurysm of the sinuses of Valsalva (right coronary sinus is the most common), patent ductus arteriosus, aortic coarctation, aortic arch hypoplasia or interruption are the commonest lesions which complicate ventricular septal defect seen as the primary lesion.
In the presence of complex anatomical situations (e.g., like multiple ventricular septal defects), associated cardiac malformations (e.g., aortic coarctation or aortic arch interruption) or in patients very ill because of repeated infections and/or associated non-cardiac malformations, the palliative approach with pulmonary artery banding can be considered as an alternative. Pulmonary artery banding can be accomplished with the conventional technique of implanting a tape around the main pulmonary artery or with a telemetrically adjustable device (FloWatch®, EndoArt, Lausanne, Switzerland).

For the surgical repair, the defect is generally closed with a patch (heterologous pericardium, PTFE, Dacron, Teflon) sutured with interrupted or running sutures, according to the surgeon’s preferences. Direct closure with pledgeted interrupted sutures (reinforced) is used only for very small defects.

- **Perimembranous ventricular septal defect:**
  - patch closure of the defect through a right atriotomy with tricuspid valve retraction (or rarely disinsertion),
  - patch closure through right ventriculotomy in case of associated infundibular obstruction requiring right ventriculotomy for relief.

- **Muscular ventricular septal defect:**
  - patch closure of the defect through a right atriotomy with tricuspid valve retraction,
  - more rarely through a right ventriculotomy,
  - very rarely through an apical left ventriculotomy.

- **Doubly committed juxtaarterial ventricular septal defect:** patch closure of the defect through a right atriotomy with tricuspid retraction or through an aortotomy or through an incision of the main pulmonary artery, based on the position of the defect and its relationship with the semilunar valves, with the need for treatment of prolapsed aortic leaflet or of a right ventricular outflow tract enlargement, and with the size of the ascending aorta.

- **Multiple ventricular septal defects:**
  - multiple or large single patch closure of the defects through a right atriotomy,
  - more rarely through a right ventriculotomy,
  - very rarely through an apical left ventriculotomy.

### Preoperative information

Transthoracic echocardiography is the primary diagnostic imaging modality in patients with suspected or known ventricular septal defects, in order to provide information on the location and extent of the defect, and on the potential presence of associated cardiac malformations. Echocardiography is usually also sufficient for the decision-making process related to the patient's management.

MRI and CT scan can be useful in defining the location of the ventricular septal defect in order to distinguish between perimembranous ventricular septal defect (Fig. 3.6.1), muscular (Fig. 3.6.2), doubly committed juxtaarterial, and inlet type of ventricular septal defect.

---

**Fig. 3.6.1.** Ventricular septal defect. CT scan, axial view, showing a large perimembranous subaortic ventricular septal defect (arrow) (Ao aorta, LA left atrium, LV left ventricle, PVs pulmonary veins, RV right ventricle)
MRI is useful to noninvasively quantify the intracardiac shunt, specially in the presence of small ventricular septal defects with borderline indications for repair, as well as in patients with a poor acoustic window for echocardiography.

MRI in fact, thanks to its capability to 3-dimensionally image the intracardiac anatomy with high resolution, can also provide useful anatomical details on the ventricular septal defect, particularly related to its position as well as its relationship to adjacent key structures, such as atrioventricular or semilunar valves, and the potential association of intracardiac lesions, such as prolapsed aortic valve leaflets. This can be particularly useful for the decision-making process with respect to the choice of the technique to close the ventricular septal defect.

Fig. 3.6.2. Ventricular septal defect. CT scan, axial 4-chamber view, showing a midmuscular ventricular septal defect (arrows) (LA left atrium, LV left ventricle, RA right atrium, RV right ventricle)

Fig. 3.6.3. Muscular ventricular septal defect. MRI fast spin echo 4-chamber view (a) showing a small muscular ventricular septal defect (asterisk); the same defect viewed en face from the right ventricular aspect in fast spin echo (b) and cine steady-state free precession (c). The left-to-right shunt (QP/QS) evaluated by phase velocity mapping at the aortic and pulmonary artery level was 1.4:1. This defect was scheduled for percutaneous interventional closure (Ao aorta, LV left ventricle, RA right atrium, RV right ventricle)
percutaneous interventional or surgical technique, or in case of complex anatomy.

To achieve these goals the cardiac MRI protocol is the following:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the “Introduction”),
- ECG-gated cine steady-state free precession sequences for quantitative assessment of both ventricular dimensions and function, and for calculation of stroke volumes, following the steps as indicated in the “Introduction”,
- ECG-gated cine steady-state free precession and fast spin echo sequences on additional planes are often required to better

---

**Fig. 3.6.4.** Perimembranous ventricular septal defect. MRI fast spin echo 3-chamber view of perimembranous septal defect (asterisk), partially closed by fibrous accessory tissue (arrow). The left-to-right shunt (QP/QS) evaluated by phase velocity mapping was 1.2:1. The left ventricular volume was in the normal range (Z-value in diastole = +1) (LA left atrium, LV left ventricle)

**Fig. 3.6.5.** Ventricular septal defect, status post pulmonary artery banding. CT scan, axial projection, showing the indentation of the pulmonary artery banding on the main pulmonary artery (arrows)

**Fig. 3.6.6.** Multiple ventricular septal defect, status post pulmonary artery banding. Cine steady-state free precession right ventricular outflow tract MRI showing a narrow pulmonary banding (asterisk) (RV right ventricle)

**Fig. 3.6.7.** Small residual ventricular septal defect. Cine gradient MRI 3-chamber view showing a narrow jet (arrow) through a small residual leak around the patch used to close the ventricular septal defect. The left-to-right shunt (QP/QS) evaluated by phase velocity mapping was 1.45:1 (Ao aorta, LV left ventricle, RV right ventricle)
define the anatomy of the ventricular septal defect along its axis and en face as well as its relationship with the great arteries, the atrioventricular valves and the adjacent structures; however very small defects may be difficult to resolve. In these cases, since turbulent high velocity flow is always present, it can be useful to use gradient echo enhanced sequences (instead of steady-state free precession), provided that the echo time is long enough to allow for sufficient spin de-phasing.

Fig. 3.6.8. Ventricular septal necrosis, status post closure of ventricular septal defect. Post gadolinium delayed enhancement MRI after surgical closure of a ventricular septal defect, showing a large area of transmural fibrosis (a, b) in the anterior part of the interventricular septum (arrows) corresponding to a dyskinetic area at the cine sequence (LV left ventricle, RV right ventricle)

Fig. 3.6.9. Iatrogenic superior vena cava occlusion, status-post closure of ventricular septal defect. Time of Flight multi-planar reformatted MRI sagittal (a) and coronal (b) view of iatrogenic complete occlusion of the Superior Vena Cava after surgical closure of ventricular septal defect. Note the dilated azygos vein draining all the superior systemic venous return. Respiratory symptoms were due to the right bronchial compression by the dilated azygos vein, as illustrated in the para-axial Fast Spin Echo imaging (c).

LV = left ventricle, RA = right atrium, SVC = superior vena cava
ECG-gated double-oblique cine steady-state free precession and fast spin echo sequences on two perpendicular planes can visualize the left ventricular outflow tract and provide details of perimembranous ventricular septal defect (Figs. 3.6.3 and 3.6.4),

ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery and ascending aorta to assess the QP/QS, and the potential presence of aortic valve regurgitation,

Potential complications

Residual or recurrent ventricular septal defect, complete atrioventricular block, pulmonary arterial hypertensive crisis, residual or recurrent aortic valve regurgitation.

Postoperative follow-up

Clinical and echocardiographic evaluations are usually sufficient in the postoperative follow-up of ventricular septal defects. CT scan and particularly cardiac MRI could be useful to show the result of palliation with pulmonary artery banding (Figs. 3.6.5 and 3.6.6), to quantify a residual intracardiac shunt (Fig. 3.6.7), to demonstrate the presence and quantify a residual/recurrent aortic regurgitation, and in case of unusual iatrogenic postoperative complications (Figs. 3.6.8 and 3.6.9).

**Chapter 3.7 Tetralogy of Fallot**

**Definition**

In anatomic terms, the malformation is characterized by four constant features: subpulmonary infundibular stenosis, ventricular septal defect, rightward deviation of the aortic valve with a biventricular origin of its leaflets, and right ventricular hypertrophy.

Although all hearts have comparable features, the malformation represents a morphological spectrum, with one morphological hallmark which unifies the overall entity: the anterocephalad deviation of the infundibular septum, the muscular structure separating the subaortic and pulmonary outlets, relative to the rest of the muscular septum.

Although unified in the sense of the septal malalignment, the patients with tetralogy of Fallot have significant variations in the precise anatomy of the ventricular septal defect, the nature of pulmonary infundibular and valvular stenosis, and the degree of aortic override, which account for the differences in hemodynamic consequences.

The ventricular septal defect is located in the membranous septum; it is subaortic and sometimes extends to the subpulmonic valve area. The ventricular septal defect is large, at least as large as the aortic valve, causing equalization of left and right ventricular pressures. The right ventricular outflow tract is hypoplastic and almost always obstructive. Occasionally at birth the right ventricular outflow tract shows no significant obstruction and results in the so-called “pink” tetralogy of Fallot. The pulmonary valve annulus is typically small in tetralogy of Fallot and the leaflets are deformed. In contrast to pulmonary valvular stenosis, the main pulmonary artery and the branch pulmonary arteries are small. There might be branch pulmonary artery stenosis as well as peripheral pulmonary artery stenosis in addition to the right ventricular outflow tract and pulmonary valvular stenosis. Bronchial arterial collaterals which connect to the peripheral pulmonary arteries are sometimes present. The main pulmonary artery is occasionally atretic and the pulmonary arteries are fed either by patent ductus arteriosus or collateral vessels. The aortic valve is typically large.

The most frequently associated anomalies are atrial septal defect or patent foramen ovale (40% of the patients), right aortic arch (25%), anomalous coronary arteries (10%), persistent left superior vena cava (8%), and major aortopulmonary collateral arteries with an extremely variable incidence, mostly correlated with the degree and duration of the cyanosis. Other associated malformations rarely reported are anomalous pulmonary venous connection, supravalvular mitral stenosis, cor triatriatum, atrioventricular septal defect, multiple ventricular septal defects, restrictive ventricular septal defect, hypoplastic or absent infundibular septum, fibromuscular subaortic stenosis, valvular aortic stenosis, valvular aortic regurgitation, aortopulmonary window, patent ductus arteriosus, aortic coarctation, vascular ring, non-confluent pulmonary arteries, and anomalous origin of the left subclavian artery.
## Surgical options

### Palliative treatment:
Systemic-to-pulmonary artery shunt, consisting in a classical (nowadays almost abandoned) or modified Blalock-Taussig anastomosis with interposition of a PTFE tubular prosthesis between the subclavian artery and the ipsilateral pulmonary artery.

### Repair:
Consists of two main steps: a) patch closure of the ventricular septal defect from a transatrial-transpulmonary or from transventricular approach with longitudinal ventriculotomy; b) right ventricular outflow tract reconstruction. This can be performed with different techniques:
- From the right atrium and/or from the pulmonary artery (transatrial-transpulmonary approach) or from the right ventricle (transventricular approach): incision with resection of the heavy trabeculations that bind the infundibular septum to the anterior right ventricular wall,
- Infundibular (pericardial or synthetic) patch enlargement (transventricular approach),
- Transannular (pericardial or synthetic, with or without monocusp) patch enlargement (transatrial-transpulmonary and transventricular approach) in case of inadequate size of the pulmonary valve annulus, measured with Hegar dilators, after pulmonary valvotomy performed from the pulmonary artery (transatrial-transpulmonary approach) or from the right ventricle (transventricular approach),
- Pulmonary arteries enlargement in case of inadequate size (measured with Hegar dilators), with prolongation of the transannular patch in case of an inadequate left pulmonary artery, with a separate patch in case of inadequate right pulmonary artery,
- Valved conduit, generally biologic, interposed between the right ventriculotomy and the pulmonary artery bifurcation, to bypass an anomalous coronary artery.

## Pre-operative information

In addition to the demographic and clinical data, the following morphologic information is required in order to plan surgical repair:
- Size and morphology of entire right ventricular outflow tract, the pulmonary valve and annulus, the main pulmonary artery and its branches (Figs. 3.7.1 and 3.7.2),
- The origin and course of the main coronary arteries (Fig. 3.7.3), particularly the presence of a major branch crossing the infundibulum,
- The end-diastolic volume of the left ventricle.

To better plan a palliative procedure, generally a modified Blalock-Taussig shunt, the following information is required:
- The side of the aortic arch (Fig. 3.7.2c),
- Presence of an anomalous subclavian artery,
- Size and morphology of the pulmonary arteries, and in particular the presence of stenotic origin of one of them (Figs. 3.7.2c and 3.7.4).

---

**Fig. 3.7.1.** Tetralogy of Fallot. CT scan, sagittal projection, showing severe obstruction of the right ventricular outflow tract, with practically pulmonary atresia (arrow); the size of the main pulmonary artery has been adequately maintained (diameter=9.9 mm) by the presence of functioning modified Blalock-Taussig shunt (LV left ventricle, RV right ventricle) (photograph courtesy of Dr. Mohamed Tawil)
While in infants echocardiography generally provides all the necessary diagnostic information for surgical palliation or repair, its role is limited in children and adolescents with tetralogy of Fallot, in whom the acoustic windows are frequently limited; CT scan and cardiac MRI are useful in both pre-operative and post-operative assessment of tetralogy of Fallot, with the focus of the investigations being different.

The CT scan and MRI can provide full visualization of the pulmonary arteries, particularly of the proximal segment of the left pulmonary artery, a frequent blind spot for both transthoracic and transesophageal echocardiography.

In most patients with tetralogy of Fallot, the central questions are to delineate all the sources of pulmonary blood flow (pulmonary arteries, aortopulmonary collaterals and ductus arteriosus) and the origin and course of the main coronary arteries (Fig. 3.7.3). Spin echo and 2-dimensional gradient echo cine MRI techniques provide excellent imaging of the central pulmonary arteries and major aortopulmonary collaterals. However, these MRI techniques require relatively long scan times for complete anatomical coverage, and small arteries (diameter less than 2 mm) may not be identified. Furthermore, these 2-dimensional techniques are suboptimal for imaging long and tortuous blood arteries, some of which arise from the brachiocephalic arteries or from the abdominal aorta.
trast CT scan and gadolinium-enhanced 3-di-
mensional MRI are ideally suited to image
these arteries as well as the aortic arch sided-
ness and the subclavian artery for the pre-pal-
liation evaluation (Fig. 3.7.2 c). Compared
with conventional angiography, MRI have
proved to be highly accurate in depicting all
sources of pulmonary blood flow in patients
with complex pulmonary stenosis or atresia,
including infants with multiple small aorto-
pulmonary collaterals.

When the origin and proximal course of
the left and right coronary arteries are not
known from other previous imaging studies,
they should be imaged either by a gradient
echo sequence designed for coronary imag-
ing or by a fast spin echo sequence. Particu-
lar attention should be paid to rule out the
presence of a major coronary artery crossing
the right ventricular outflow tract.

The cardiac MRI protocol currently used
in patients with tetralogy of Fallot is the fol-
lowing:
- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angio-
graphy (see the appendix in the “Intro-
duction”),
- ECG-gated cine steady-state free preces-
sion sequences in 2-chamber, 4-chamber
planes, and ventricular short axis for the
quantitative assessment of both ventricu-
lar dimensions, function and stroke vol-
ume, as illustrated in the appendix of the
“Introduction”,
- ECG-gated cine steady-state free preces-
sion and static fast spin echo sequences
on additional planes to better delineate
the morphology of the right ventricular
outflow tract,
- ECG-gated static isotropic 3-dimensional
steady-state free precession for the evalua-
tion of origin and proximal course of the
coronary arteries,
- Gadolinium-enhanced 3-dimensional MRI
for the evaluation of the pulmonary ar-
teries, as well as the side of the aortic
arch and any abnormal source of pulmo-
nary blood flow.

Potential complications

- Palliation (systemic-to-pulmonary artery
shunt): inadequate pulmonary blood flow
(insufficient, excessive or nonhomogeneous),
pulmonary artery distortion, inadequate
growth of the pulmonary arteries, acquired
pulmonary atresia.
- Repair: residual or recurrent ventricular
septal defect (patch dehiscence or separate
defect), residual or recurrent right ventricu-
lar outflow tract obstruction, complete atrio-
ventricular block, arrhythmias, aneurysm of
right ventricular outflow patch, pulmonary
valve insufficiency.

Late complications after repair:
- pulmonary valve regurgitation: long stand-
ing pulmonary valve regurgitation, particu-
larly after repair with transannular patch
enlargement, can determine right ventricu-
lar dilatation and failure, with or without
subsequent tricuspid valve regurgitation,
requiring re-operation to insert a valve or
a biological valve conduit in pulmonary
valve position,
- arrhythmias: supraventricular and ventricu-
lar arrhythmias can occur years after re-
pair, requiring treatment.
Post-operative follow-up

**After palliation:** Because the course of tortuous arteries of variable caliber can be seen in a single image, multidetector row CT or cardiac MRI with multiplanar and 3D volume rendering images are valuable to facilitate the identification of surgically created systemic-to-pulmonary artery shunts and the relationships of the shunts to the heart and to the pulmonary arteries (Fig. 3.7.5), and the presence of stenosis or kinking along the tubular prosthesis (Figs. 3.7.6 and 3.7.7).

Post-operative CT or MRI can demonstrate the presence of a false aneurysm at the level of the subclavian artery origin of a modified Blalock-Taussig shunt.

In the presence of a perigraft seroma (sterile collection of fluid in a nonsecretory wall surrounding the tubular prosthesis used for a modified Blalock-Taussig shunt), the conventional radiographic investigations show an opacification of the lung on the ipsilateral side of the modified Blalock-Taussig shunt, indistinguishable from lung atelectasis or infection, and a widening of the superior
mediastinum. CT investigation instead can show a fluid collection of intermediate intensity surrounding or adjacent to the tubular prosthesis. After the administration of I.V. contrast medium, the capsule of the peri- graft seroma shows slight enhancement, and the tubular prosthesis itself can be seen as a hyperdense structure adjacent to or trans- versing the perigraft seroma.

**After repair:** CT scan in the post-operative period can investigate the presence, the location and the extent of stenosis of the pulmonary arteries and also show the presence of an aneurysm of the right ventricular outflow tract, calcifications either in the right ventricular outflow tract or in the biological conduit used to reconstruct the continuity between the right ventricle and the pulmonary artery (Fig. 3.7.8).

Cardiac MRI is extensively used to assess patients of all ages after repair of tetralogy of Fallot, but its greatest clinical utility is in older children, adolescents and adults. Quantitative assessment of right and left ventricular dimensions and function is a key element of cardiac MRI evaluation in these patients. The presence and degree of right ventricular dysfunction is an important de-
terminant of clinical status late after repair of tetralogy of Fallot, and right ventricular dysfunction is also closely correlated with left ventricular dysfunction, likely through ventricular-ventricular interactions. The degree of pulmonary valve regurgitation measured by PVC-MRI (Fig. 3.7.9) is closely correlated with the degree of right ventricular dilation. Another factor affecting right ventricular function is the presence and extent of an aneurysm in the right ventricular outflow tract (Figs. 3.7.10–3.7.12).

Another technique increasingly used in these patients is post-gadolinium myocardial delayed enhancement for assessment of myocardial fibrosis (Fig. 3.7.13). The clinical significance of positive myocardial delayed enhancement in patients after repair of tetralogy of Fallot still requires further studies.

The goals of the cardiac MRI examination, therefore, include the following: quantitative assessment of left and right ventricular volumes, mass, stroke volumes, and ejection fraction; imaging of the morphology of the right ventricular outflow tract, pulmonary arteries, aorta, and aortopulmonary collaterals; quantification of pulmonary valve regurgitation, tricuspid regurgitation, pulmonary-to-systemic flow ratio (QP/QS) if there is a residual intracardiac shunt, and finally distribution of the pulmonary blood flow.

In patients after surgery for tetralogy of Fallot, the following cardiac MRI protocol is used:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix of the “Introduction”),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume as illustrated in the appendix of the “Introduction”,
- ECG-gated cine steady-state free precession sequence on both frontal and sagittal view to evaluate the right ventricular outflow tract,

Fig. 3.7.9. Tetralogy of Fallot, status-post repair, pulmonary valve regurgitation. MRI quantification of the pulmonary valve regurgitation. a Sagittal projection, steady-state free precession of right outflow tract. A PVC MRI is prescribed perpendicular to the right outflow tract (white line). b Flow volume curve shows severe pulmonary valve regurgitation, with pulmonary regurgitation fraction = 51%
ECG-gated cine steady-state free precession sequence along the long axis of both pulmonary arteries,
ECG-gated cine steady-state free precession sequence double oblique 3-chambers for the evaluation of the left ventricle outflow tract and aortic root,
Gadolinium-enhanced 3-dimensional MRI mainly for the right ventricular outflow tract and pulmonary arteries anatomy (Fig. 3.7.14), as well as for the assessment of any aortopulmonary collateral artery,
ECG-gated PVC-MRI sequences perpendicular to the main, right and left pulmonary arteries and ascending aorta, and atrioventricular valves in order to assess flow patterns,
Post-gadolinium delayed myocardial enhancement may be used to evaluate the presence of scar tissue (Fig. 3.7.13).

Fig. 3.7.10. Tetralogy of Fallot, status post repair with a transannular patch. MRI fast spin echo (black blood), para-coronal (a) and para-sagittal (b) projections showing the right ventricular outflow tract. c 3-dimensional volume rendering MR angiography showing right ventricular outflow tract and pulmonary arteries with adequate size and morphology (LPA left pulmonary artery, LV left ventricle, MPA main pulmonary artery, RPA right pulmonary artery, RV right ventricle)

Fig. 3.7.11. Tetralogy of Fallot, status post repair with trans-annular patch. MRI steady-state free precession para-coronal right ventricular outflow tract (a) and main intensity projection MR angiography (b) showing a dilated infundibulum (RV right ventricle)
The timing of re-operation for reconstruction of right ventricular outflow tract in patients with previous repair of tetralogy of Fallot is still a matter of debate: ideally the indication should be not too late because of the risk of irreversible right ventricular dysfunction and fatal arrhythmias, but not too early because of the limited durability of any biological device used for right ventricular outflow tract reconstruction, particularly in young children.

Thanks to the use of cardiac MRI in a subset of patients, some cut-off points related to the indexed right ventricular volumes and ejection fractions are emerging for the indication to implant a pulmonary valve in the right ventricular outflow tract. However, the end-points of these cut-offs are generally based on the complete post-operative recovery of the right ventricular size to the normal value; this is not a suitable goal, when by dealing with patients who have un-

Fig. 3.7.12. Tetralogy of Fallot, status post repair, infundibular aneurysm. MRI with fast spin echo (black blood) para-coronal right ventricular outflow tract (a) and 3-dimensional volume rendering angiography (b) showing an aneurysm of the infundibular patch (arrow) (Inf infundibular, RV right ventricle)

Fig. 3.7.13. Tetralogy of Fallot, status post repair. MRI sagittal projection (a), 3-chamber view (b) and ventricular short axis (c) showing the white strip appearance of the infundibular patch (white arrow) and of the patch for ventricular septal defect closure (black arrow), demonstrating delayed enhancement (AO aorta, LV left ventricle, RV right ventricle)
dergone repair of tetralogy of Fallot, who had patch closure of the ventricular septal defect and another patch to enlarge the infundibulum. Moreover many other variables should be taken into consideration, such as right ventricular outflow tract with transannular patch extension with or without aneurysm, tricuspid valve regurgitation, elevated right ventricular systolic and/or diastolic pressure, and left ventricular function as well their evolution over time and other clinical and electrophysiological variables.

Thus, due to the accuracy of parameters and information obtained by cardiac MRI (some of which are not available by any other diagnostic investigation), nowadays it is inconceivable to make any decision on patients operated on for repair of tetralogy of Fallot without a previous targeted cardiac MRI investigation.

References
**Definition**

This is an uncommon variation of tetralogy of Fallot with a ring-like and usually stenotic malformation (rather than absence) of the pulmonary valve, with failure of the development of valve cusps. The central pulmonary arteries are usually hugely dilated or aneurysmal. The pulmonary artery dilatation may extend beyond what is expected from severe pulmonary regurgitation to several generations of pulmonary arteries causing tracheobronchial compression; this often results in either hyperexpansion from air trapping or collapse of lobes, or even an entire lung. The ductus arteriosus is generally absent. The intracardiac anatomy generally presents with the same characteristics of tetralogy of Fallot (see chapter “Tetralogy of Fallot”) except that the right ventricular outflow tract is not excessively restrictive.

**Associated anomalies**

Atrial septal defect, common atrioventricular valve (rare), tricuspid atresia (rare), intact ventricular septum (rare), transposition of the great arteries (rare), agenesis of the ductus arteriosus, branch pulmonary arteries anomalies (non-confluent pulmonary arteries), right aortic arch (frequent), anomalous coronary arteries, dextrocardia and situs inversus (very rare).

**Surgical options**

The surgical repair consists of the following steps. Excision of the main pulmonary artery, with transection of its proximal end just above the pulmonary valve annulus and of its distal end at the level of the bifurcation. Resection and plication of the aneurysmal pulmonary arteries, extended laterally to the hilum, with or without including the plication of the posterior wall of both pulmonary arteries. Transannular longitudinal right ventriculotomy. Patch closure of ventricular septal defect from longitudinal right ventriculotomy. Valved conduit (homograft or heterograft) interposition between the right ventricle and the reconstructed pulmonary arteries bifurcation.

**Pre-operative information**

Pre-operative information in patients with tetralogy of Fallot with absent pulmonary valve is similar to that required in patients with tetralogy of Fallot (see relative chapter), with particular attention focused on potential airway obstruction due to dilated pulmonary artery branches and the frequent association of the right aortic arch. Both CT scan (Fig. 3.8.1) and MRI can provide clear imaging of the dilated pulmonary arteries and their relationship with the airways.
Potential complications

Residual or recurrent ventricular septal defect (patch dehiscence or separate defect), residual or recurrent right ventricular outflow tract obstruction, complete atrioventricular block, arrhythmias, airway compression, respiratory insufficiency.

Post-operative follow-up

As for the pre-operative information, in patients with tetralogy of Fallot with absent pulmonary valve the goals of the post-operative investigations are similar to the ones required in patients with tetralogy of Fallot (see relative chapter), again with particular attention focused on potential airway obstruction due to the dilated pulmonary arteries branches and the surgical technique utilized. Again both CT scan (Fig. 3.8.2) and MRI (Fig. 3.8.3) are able to evaluate the results of the different surgical techniques.

<thead>
<tr>
<th>Surgical options</th>
</tr>
</thead>
<tbody>
<tr>
<td>The right ventricular size and function dictate the possibility of surgical management with respect to biventricular or univentricular type of repair, or one-and-half ventricular repair. Surgical pulmonary valvotomy can be performed with or without a systemic-to-pulmonary arterial shunt depending upon the right ventricular size and function. If the right ventricle is small, a systemic-to-pulmonary arterial shunt is necessary to provide pulmonary blood flow until antegrade flow through the pulmonary valve becomes adequate. However, if the pulmonary arteries are not small, then pulmonary valvotomy alone may be adequate, with or without a postoperative period with maintained prostaglandin E infusion. Decompression of the right ventricle by pulmonary valvotomy may cause reversal of flow in the coronary arteries to sinusoids, leading to poor myocardial perfusion. This is especially true in the presence of right ventricular dependent coronary circulation, particularly in the presence of coronary artery stenosis. Therefore, right ventricular decompression should not be performed if coronary artery stenoses are demonstrated with sinusoids. In patients with small pulmonary arteries treated with a systemic-to-pulmonary artery shunt, if the right ventricle continues to be small and inadequate, then a cavopulmonary connection may be required. Patients with severe right ventricle-to-coronary arteries sinusoids may require cardiac transplantation. Sinusoids are typically not present in patients with severe tricuspid insufficiency and a normal right ventricular size. In patients with significant tricuspid valve regurgitation and low right ventricular pressure, pulmonary valvotomy may not result in effective forward flow through the right ventricle because of tricuspid valve regurgitation.</td>
</tr>
</tbody>
</table>
Pre-operative information

The information required to make the decision about surgical treatment include the size, morphology and function of the right ventricular cavity, the tricuspid size and function, the presence and extension of the myocardial sinusoids, the size and shape of the patent ductus arteriosus as the only source of pulmonary blood flow, and the morphology of the pulmonary arteries (Figs. 3.9.1–3.9.3). Transthoracic echocardiography is generally exhaustive for preoperative evaluation of neonates with pulmonary atresia with intact ventricular septum. Conventional angiography could be indicated in case of suspected myocardial sinusoids not seen with echocardiography.

CT scan, sagittal oblique, showing the hypoplastic right ventricle and the confluent pulmonary arteries with long and tortuous patent ductus arteriosus (arrows) (AA aortic arch, AAo ascending aorta, LA left atrium, LPA left pulmonary artery, LV left ventricle, MPA main pulmonary artery, PV pulmonary veins, RPA right pulmonary artery, RV right ventricle) (photograph courtesy of Dr. Mohamed Tawil)

Fig. 3.9.2. Pulmonary atresia with intact ventricular septum. a CT contrast angiography, axial view, showing a major myocardial sinusoid (arrows) coming from the hypoplastic right ventricle and reaching the left anterior descending coronary artery. b CT scan of the same neonate with 3-dimensional reconstruction, showing the major myocardial sinusoid (arrows) coming from the hypoplastic right ventricle and reaching the left anterior descending coronary artery (AAo ascending aorta, DTAo descending thoracic aorta, LAD left anterior descending coronary artery, LPA left pulmonary artery, PDA patent ductus arteriosus, RPA right pulmonary artery) (photographs courtesy of Dr. Mohamed Tawil)
Potential complications

Inadequate or inhomogeneous pulmonary blood flow, poor myocardial perfusion, myocardial infarction, residual tricuspid valve regurgitation, right heart failure.

Post-operative follow-up

Patients with pulmonary atresia with intact ventricular septum after the first stage of treatment (pulmonary valvotomy and/or systemic-to-pulmonary shunt), depending on the morphology and function of the right heart (tricuspid valve, right ventricle, pulmonary valve and arteries) are candidate for univentricular or biventricular or one-and-half ventricular repair. In borderline cases MRI can be useful in the decision-making process by evaluating the right ventricular volume and function, pulmonary blood flow and degree of residual pulmonary valve regurgitation.

After one-and-half ventricular repair, in addition to the previous goals and to the evaluation of the cavopulmonary anastomosis, MR angiography can identify potential veno-venous collaterals between superior and inferior vena cava and even quantify them by means of phase contrast velocity acquisition at both inferior and superior vena cava level (Fig. 3.9.6).

The evaluation of univentricular repair has already been described in the relative chapter (see “Single ventricle”).

The following protocol is used for post-operative evaluation in these patients:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix of the “Introduction”),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume as illustrated in the appendix of the “Introduction” (Fig. 3.9.4),
Fig. 3.9.4. Pulmonary atresia with intact ventricular septum, status post one-and-half ventricular repair. MRI cine steady-state free precession ventricular short-axis projection showing a very trabeculated and mildly dilated (100 mL/m² B.S.A.) right ventricle (LV left ventricle, RV right ventricle)
ECG-gated cine steady-state free precession sequence for right ventricle 2-chamber view,

ECG-gated cine steady-state free precession sequence on sagittal view to evaluate the right ventricular outflow tract (Fig. 3.9.5),

ECG-gated cine steady-state free precession and fast spin echo sequence to visualize the cavopulmonary anastomosis,

gadolinium-enhanced 3-dimensional MRA of the right ventricular outflow tract and pulmonary arteries morphology, as well as for the assessment of veno-venous collateral and cavopulmonary anastomosis (Figs. 3.9.6 and 3.9.7),

ECG-gated PVC-MRI sequences perpendicular to the main pulmonary artery (also to quantify the pulmonary valve regurgitation), ascending aorta, superior and inferior vena cava,

**Definition**

Ebstein’s anomaly is a congenital malformation of the tricuspid valve and right ventricle characterized by several features, each of which can exhibit a spectrum of malformations relevant to the surgical management of the condition:

- Displacement of the septal and posterior leaflets of the tricuspid valve towards the apex of the right ventricle, with adherence to the myocardium,
- Anterior leaflet attached to the appropriate level of the tricuspid valve annulus, however, redundant, larger than normal and with multiple fenestrations and chordal attachments to the ventricular wall,
- Segment of the right ventricle from the level of true tricuspid annulus to the level of attachment of the septal and posterior leaflets unusually thin and dysplastic, and described as “atrialized”; right atrio-ventricular junction (being the true tricuspid valvular annulus) and right atrium extremely dilated,
- Cavity of the right ventricle, beyond the atrialized portion, reduced in size, usually with lack of an inlet chamber, and with a small trabecular component,
- Infundibulum often obstructed by the redundant tissue of the anterior leaflet as well as by the chordal attachments of the anterior leaflet to the infundibulum,
- Variable type and degree of ventricular dysfunction.

Each heart with Ebstein’s malformation is different, and there is an infinite variability that can occur with the above mentioned characteristics.

Carpentier classified four clinical variants with progressively increasing severity:

- **Type A**: the volume of the true right ventricle is adequate,
- **Type B**: the volume of the right ventricle is small, and there is a large atrialized portion of the right ventricle,
- **Type C**: the volume of the right ventricle is small, with right ventricular outflow tract obstruction,
- **Type D**: there is almost complete atrialization of the right ventricle with the exception of a small infundibular component, and the only communication between the atrialized ventricle and the infundibulum is through the anteroseptal commissura of the tricuspid valve.

The most common associated anomaly is atrial septal defect, occurring in about 50% of cases, often causing cyanosis due to right-to-left shunt at the atrial level. There is a variable degree of right ventricular outflow tract obstruction. A Wolff-Parkinson-White type of accessory pathway, often with associated pre-excitation, is present in about 10% of cases. In symptomatic neonates, survival is dependent on the presence of a patent ductus arteriosus. Rare associated anomalies are abnormality of the ventriculoarterial connection or double discordance (atrioventricular and ventriculoarterial), atrioventricular septal defect, ventricular septal defect, tetralogy of Fallot, and aortic coarctation.
**Surgical options**

The surgical repair includes:
- closure of the atrial septal defect,
- plication of the atrialized portion of the right ventricle,
- repair or replacement of the tricuspid valve.

As tricuspid repair is based predominantly on a satisfactory arrangement of the anterior leaflet, its feasibility and result mainly depends on the presence of a mobile and free leading edge of the anterior leaflet. In patients with reduced size or function of the right ventricle, a one-and-half ventricular repair is performed, with end-to-side anastomosis of the superior vena cava to the right pulmonary artery in addition to intracardiac repair, in order to reduce the volume overload of the small/malfunctioning right ventricle. Exceptionally, a total cavopulmonary connection (univentricular repair) is required for patients with an extremely small or malfunctioning right ventricle. Pre-operative electrophysiology for bypass pathways is necessary in order to perform intraoperative ablation. When ventricular pacing is required, it should be done through epicardial leads rather intravenously, since the tricuspid valve function is already compromised.

**Pre-operative information**

Echocardiography is generally sufficient for diagnosis and evaluation of Ebstein's anomaly. However, there are aspects that need to be considered:
- it is remarkably difficult to understand from 2-dimensional echocardiography alone the arrangement of the tricuspid leaflets and their tension apparatus (mainly for the surgical implications). However 3-dimensional echocardiography offers new insight into the morphology and function of a malformed tricuspid valve and allows elucidation of all the features mentioned above. In our opinion as this technique will gain widespread diffusion it will become the best tool in the selection of patients for surgery and in planning the surgical approach.
- both right and/or left myocardial dysfunction can be present; thus, assessment of ventricular function by 2-dimensional echocardiography, albeit of crucial importance in some cases, can be inaccurate, due to unusual right ventricular anatomy and septal displacement. Therefore, as an alternative cardiac MRI is useful to estimate right and left ventricular volume, function and potential myocardial thinning, in addition to visualizing the inter-atrial septum and measuring the right atrial volume.

The cardiovascular MRI protocol currently used in Ebstein's anomaly is the following:
- 3-plane localizing images,
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes (Fig. 3.10.1), and ventricular short axis for the quantitative assessment of both ventricular dimensions, function, stroke volume (as illustrated in the appendix in the “Introduction”) and potential right ventricle myocardial thinning,
- ECG-gated cine steady-state free precession and static fast spin echo sequences on additional planes to better determine the anatomy of the right ventricular outflow tract,
- ECG-gated cine steady-state free precession and fast spin echo in axial and coronal plane for the evaluation of the tricuspid valve (Fig. 3.10.2), the posterior leaflet being better imaged in a coronal or oblique-coronal orientation,
- ECG-gated cine steady-state free precession and fast spin echo in oblique-sagittal orientation at the fossa ovalis level to better delineate the potential atrial communication,
- ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending aorta, to assess QP/QP and particularly the right-to-left shunt.
Potential complications

Residual or recurrent atrial septal defect, residual or recurrent (or surgically induced) tricuspid valve stenosis or insufficiency, complete atroventricular block, right coronary artery obstruction during the process of plication, right ventricular dysfunction, left ventricular dysfunction.

Post-operative follow-up

Right and left ventricular end-diastolic and end-systolic volume indexes can be measured and compared with the pre-operative values, as well as the tricuspid valve function.

Definition

The ductus arteriosus connects the aortic arch opposite the left subclavian artery to the left pulmonary artery. Patent ductus arteriosus, when it closes, usually does so beginning from the pulmonary artery end, leaving a diverticulum on the aortic side (Kommerel diverticulum) which eventually closes. The patent ductus arteriosus is connected to the left pulmonary artery even in the presence of a right aortic arch. Rarely, however, it connects to the right pulmonary artery. Bilateral patent ductus arteriosus has very rarely been observed.

Associated anomalies

Atrial septal defect, atrioventricular septal defect, ventricular septal defect, aortic coarctation, tetralogy of Fallot, transposition of the great arteries and the group of ductus-dependent congenital heart defects: hypoplastic left heart, aortic arch interruption, pulmonary atresia with intact ventricular septum.

Surgical options

The surgical procedure is performed through a left posterolateral thoracotomy without cardiopulmonary bypass; occasionally, in adults with large hypertensive patent ductus arteriosus with calcification on the ductal wall, cardiopulmonary bypass may be utilized.

In the case of repair of associated lesions with cardiopulmonary bypass from the median sternotomy, the repair of patent ductus arteriosus is performed through a transmediastinal approach. In this case, the ductus is exposed by dissecting along the superior aspect of the pulmonary artery bifurcation and is closed at the beginning of cardiopulmonary bypass. After careful dissection from the adjacent tissues, closure of the patent ductus can be obtained by means of ligature or surgical division between two vascular clamps and anastomosis of the two ductal stumps.

In premature neonates, due to the extreme friability of the ductal tissue, extensive dissection in the area of the patent ductus is avoided and closure is accomplished with a metal clip.

Pre-operative information

Isolated patent ductus arteriosus is generally fully diagnosed by echocardiography and is considered a Class III indication for CT scan or MRI, mainly in neonates and infants. However both CT and MRI can provide more precise anatomical and morphologic details of the patent ductus arteriosus (Figs. 3.11.1 and 3.11.2). Using multiplanar CT reformations, the location, caliber, length and morphology of the patent ductus arteriosus can be assessed in isolated defects as well in complex malformations.

In adult patients, the presence and degree of calcifications of the wall of patent ductus arteriosus can be shown.

MRI is useful particularly in the case of aneurysm formation (Fig. 3.11.3) or in association with a potential co-existing great ar-
Fig. 3.11.1. Patent ductus arteriosus. CT scan in a patient with transposition of the great arteries, 3-dimensional oblique sagittal (a) and posterior (b) view showing the patent ductus arteriosus (AAo ascending aorta, LPA left pulmonary artery, PA pulmonary artery, PDA patent ductus arteriosus, RPA right pulmonary artery) (photographs courtesy of Dr. Mohammed Tawil)

Fig. 3.11.2. Patent ductus arteriosus. MRI oblique sagittal fast spin echo (a) and gadolinium-enhanced 3-dimensional angiography (maximal intensity projection) (b) showing a small patent ductus arteriosus (*) (Ao aorta, LV left ventricle, PA pulmonary artery, RV right ventricle)
tery anomaly (Fig. 3.11.4). Cine MRI and MRI-PVC acquisitions can respectively visualize the flow jet into the main pulmonary artery (Fig. 3.11.4) and assess the amount of shunt, knowing that in the presence of patent ductus arteriosus without other shunting lesions, the systemic blood flow (QS) is equal to the main pulmonary artery flow, and pulmonary blood flow (QP) is equal to the ascending aorta flow.

In the presence of patent ductus arteriosus, we suggest the following MRI protocol:

Fig. 3.11.3. Patent ductus arteriosus aneurysm. Gadolinium-enhanced 3D MR angiography (a) maximal intensity projection and (b) volume rendering showing an aneurysm (*) of patent ductus arteriosus (Desc. Ao descending aorta, PA pulmonary artery)

Fig. 3.11.4. Patent ductus arteriosus and aortic coarctation. Oblique sagittal fast spin echo (a), gadolinium-enhanced 3-dimensional MR angiography volume rendering (b) and cine MRI (c) showing a very small patent ductus arteriosus (*) associated with aortic coarctation (Ao aorta, LV left ventricle, PA pulmonary artery)
- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angio-
  graphy (see the appendix in the “Intro-
  duction”),
- ECG-gated cine steady-state free preces-
  sion and fast spin echo sequences in the
  para-sagittal oblique and axial view at the
  level of the patent ductus arteriosus and
  great arteries (Fig. 3.11.2),
- ECG-gated phase velocity contrast MRI se-
  quences perpendicular to the main pul-
  monary artery and ascending aorta, to as-
  sess the QP/QS,
- gadolinium-enhanced 3-dimensional MR
  angiography for the evaluation of the aor-
  tic arch and patent ductus arteriosus (Fig.
  3.11.3).

Potential complications

Residual or recurrent patency (after ligature,
not after division), hemorrhage, paradoxical
arterial hypertension (in neonates), chylo-
thorax, recurrent laryngeal nerve lesion. A
late complication, extremely rare, is the for-
matation of an aneurysm.

Post-operative follow-up

CT scan and MRI are very rarely indicated
in the post-operative evaluation, unless an
aneurysm at the site of the ductus arteriosus
is suspected.

Valvular

Definition

The commissurae of the aortic valve may be fused, and the ring is occasionally small. The orifice of the aortic valve can be eccentric. The valve is commonly bicuspid in aortic stenosis and the leaflets are asymmetric in 40% of cases. There is occasionally more than one level of obstruction in the left ventricular outflow tract together with aortic valvular stenosis. About 10% of patients with aortic valvular stenosis have subvalvar aortic stenosis. Supravalvar aortic stenosis is rarely associated with aortic stenosis. In 50% of valvular aortic stenosis patients, a certain degree of aortic insufficiency is associated. Aortic valvular stenosis is not always the result of a bicuspid aortic valve, since bicuspid aortic valve is 10–20 times as common as aortic stenosis. Thus, a small number of bicuspid valves leads to aortic stenosis, but the majority will not develop into aortic stenosis. Right-to-left commissures have a worse prognosis in bicuspid aortic than anteroposterior commissures in developing aortic stenosis. Also eccentric orifices have a worse prognosis than central orifices in developing aortic stenosis.

Associated anomalies

Subvalvular and/or supravalvular obstruction, hypoplastic aortic annulus, hypoplastic aortic arch, aortic coarctation, mitral stenosis, mitral regurgitation, atrial septal defect, ventricular septal defect, patent ductus arteriosus. In neonates, the association of left ventricular hypoplasia or fibroelastosis is relatively frequent.

Surgical options

Surgical aortic valvotomy is performed accordingly with the aortic valve morphology: the fused commissurae are opened by careful incision, but without reaching the aortic wall. The obtained opening is controlled with Hegar dilators and compared with the normal size for the age and body weight.

Aortic valve replacement, where required, can be performed using conventional surgical techniques, even if in infants and children the preferred surgical option is a Ross operation (autotransplantation of the native pulmonary valve in the aortic position and right ventricle to pulmonary artery continuity obtained with a valved homograft or heterograft).

If the size of the aortic annulus is small, the enlargement of the aortic annulus can be performed with one of the following techniques:

Posterior annular enlargement

- Nicks: aortotomy extended through the noncoronary sinus and the anterior leaflet of the mitral valve; enlargement obtained with prosthetic patch,
- Managouian: aortotomy extended through the left and noncoronary sinuses and the anterior leaflet of the mitral valve; enlargement obtained with prosthetic patch.
Aortoventriculoplasty
- Konno-Rastan: aortotomy extended through the right ventricular outflow tract, aortic annulus divided between the right and left cusps, interventricular septum incised; enlargement obtained with one patch to enlarge interventricular septum, aortic annulus and aortic root, one to enlarge the right ventricular outflow tract,
- Clarke: aortoventriculoplasty performed using an aortic homograft instead of an artificial valve; the septal leaflet of the mitral valve of the homograft is used as a patch for the incised interventricular septum,
- Ross-Konno: aortoventriculoplasty performed using a pulmonary autograft.

Pre-operative information

The transthoracic and, when required, transesophageal echocardiography are generally able to accurately evaluate the anatomy and functioning of the malformed aortic valve, as well as to provide information useful for the decision-making and the timing for intervention.

According to the guidelines of the Society of Cardiac MRI, cardiac MRI is not indicated in case of isolated aortic valve stenosis. However, aortic insufficiency, due to MRI’s ability to accurately evaluate left ventricular volume and function, to identify the potential presence of fibrosis, as well as to quantify the degree of aortic valve regurgitation, is considered a class II indication. In adult patients with a bicuspid aortic valve, MRI and CT are useful to assess the size of the ascending aorta and its progressive dilatation over time. Moreover, new insights on bicuspid aortic valves are coming from cardiac MRI studies, mainly focused on the abnormal mechanical proprieties of the aortic wall in such subjects. CT scan can be also indicated for calcium detection and quantification.

The following is the cardiac MRI protocol suggested to evaluate the left ventricular outflow tract and aortic obstructions:
- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix in the “Introduction”)
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of ventricular dimensions, function, mass and stroke volume, as illustrated in the appendix of the “Introduction”,

Fig. 3.12.1. Bicuspid aortic valve stenosis. Cine MRI steady-state free precession of long axis (a) and short axis (b) showing a bicuspid aortic valve. Note the reduced opening of the aortic leaflets (LV left ventricle, MPA main pulmonary artery)
ECG-gated cine steady-state free precession para-sagittal sequence to visualize the left ventricular outflow tract, ascending aorta, and the aortic arch,

- ECG-gated cine steady-state free precession 3-chamber view, and others planes if required to visualize the left ventricular outflow tract,

- ECG-gated cine steady-state free precession and, when needed, fast echo short axis of the aortic valve and ascending aorta to evaluate the morphology, and the leaflet opening and coaptation (Figs. 3.12.1 and 3.12.2), and the wall of the proximal ascending aorta,

- ECG-gated phase velocity contrast MRI sequences perpendicular to the aortic valve and ascending aorta to evaluate the degree of aortic valve regurgitation and the flow maximum velocity,

- Gadolinium-enhanced 3-dimensional MRI if required for the evaluation of the aortic arch and the brachiocephalic vessels,

- Post-gadolinium delayed myocardial enhancement may be used to evaluate the presence of fibrotic tissue.

Potential complications

Residual or recurrent aortic valve stenosis, aortic valve regurgitation, complete atrioventricular block.

Fig. 3.12.2. Bicuspid aortic valve stenosis. MRI showing the aneurysm of noncoronary sinus of Valsalva in a steno-insufficient bicuspid aortic valve (headarrow): static fast spin echo imaging (a); cine MRI steady-state free precession (b, c) (MPA main pulmonary artery)

Post-operative follow-up

Regardless of the type of surgery, echocardiography is obviously the first diagnostic tool for the post-operative evaluation. Cardiac MRI could be required, mainly in adult patients, when echocardiography is not exhaustive or when it contradicts the clinical picture, or when more insight is required on the status of the ascending aorta, degree of aortic valve regurgitation, left ventricular function, myocardial fibrosis or in case of associated anomalies.

The MRI protocol in the post-operative follow-up is the same as in the pre-operative evaluation.

Post-operative investigations after the Ross operation are addressed to both the left and the right ventricular outflow tracts (Fig. 3.12.3). With regard to the newly constructed left ventricular outflow tract, the following information is increasingly being incorporated into the clinical imaging protocol in patients after Ross operation:

- the adequate reconstruction of the new aortic root with the position of the pulmonary autograft;

- the transplanted orifices of the coronary arteries on the pulmonary autograft (if the root replacement technique was used), with absence of kinking, twisting, compression or distortion;
the size of the aortic root and ascending aorta, and their potential progressive dilatation over time, in the cases that required size adaptation of the ascending aorta because of the presence of pre-operative dilatation, like for severe aortic valve regurgitation;

the function of the “new” aortic valve;

imaging of the coronary arteries for evaluation of proximal stenosis of the coronary arteries.

With regard to the newly constructed right ventricular outflow tract by means of either a homograft or a heterograft, the following can be determined:

- the adequate reconstruction of the new right ventricular outflow tract without narrowing at various levels; proximal anastomosis on the right ventricle, biological valved conduit itself or distal anastomosis on the pulmonary artery;
- the absence of extrinsic compression, kinking or twisting of the biological valved conduit;
- the “new” pulmonary valve function at late follow-up.

### Subvalvular

**Definition**

The subaortic obstruction can be determined by the following different morphological types:

- posterior malalignment of the outlet septum,
- asymmetric septal hypertrophy or hypertrophic cardiomyopathy,
- discrete fibromuscular diaphragm or ridge, generally close to the aortic valve,
- extensive fibromuscular tunnel with involvement of the mitral valve,
- the combination of the above.

The aortic annulus can be normal or hypoplastic.

**Associated anomalies**

Coarctation of the aorta, aortic arch interruption, mitral stenosis, ventricular septal defect, atrioventricular septal defect, double chamber right ventricle, univentricular heart.

**Surgical options**

The discrete fibromuscular diaphragm is treated by diaphragm dissection/resection with septal myotomy/myectomy. In the presence of malalignment between the left ventricular outflow tract and the ascending aorta, septal myectomy is needed in order to obtain a straight outflow and prevent recurrences.
An extensive fibromuscular tunnel is treated with one of two different techniques, depending on the size of the aortic annulus:

- **Small annulus**: aortoventriculoplasty (see above for aortic valve replacement),
- **Normal annulus**: ventricular septoplasty, generally called partial Konno-Rastan procedure, despite it being described for the first time by Cooley in 1986; the right ventricular outflow tract and the interventricular septum are incised, without incising the aortic annulus; relief of subaortic obstruction is obtained with a prosthetic patch to enlarge the interventricular septum; a second patch is required to enlarge the incised right ventricular outflow tract.

### Pre-operative information

Even more than for valvular obstruction, the transthoracic and, when required, transesophageal echocardiography, are generally exhaustive to accurately evaluate the morphology of the left ventricular outflow tract and the degree of obstruction, as well as to provide information useful for the decision-making and the timing for intervention.

Thus, CT scan and MRI (Fig. 3.12.4) are rarely used in the pre-operative evaluation of subaortic obstruction, with the exception of hypertrophic cardiopulmonary, where MRI can provide useful prognostic data, as recently reported.

### Potential complications

Residual or recurrent left ventricular outflow tract obstruction, residual or recurrent aortic valve regurgitation, mitral valve lesion, creation of ventricular septal defect, complete atrioventricular block.

### Post-operative follow-up

For the post-operative follow-up, echocardiography also provides sufficient information.

---

**Supravalvular**

### Definition

Supravalvular aortic stenosis may be localized or diffuse:

- **Localized**: usually there is an externally apparent waisting of the supravalvular area of aorta, just above or at the upper level of attachments of the valve leaflets; hourglass appearance in association with some dilatation of the sinuses of Valsalva. There is a variable amount of intimal thickening with an internal shelf which substantially increases the obstruction and may cause severe stenosis or even a complete occlusion of the origin of the left main coronary artery.
- **Diffuse**: less frequently the supravalvular narrowing is diffuse with extension through the entire ascending aorta, even beyond into the aortic arch and the origin of the brachiocephalic arteries.

### Associated anomalies

One-third of all cases have Williams-Beuren syndrome.

Thickened aortic valve leaflets but without a true valvular stenosis (30%), rarely hypo-
plastic aortic annulus or subvalvular obstruction, hypoplastic pulmonary arteries (30%), coarctation of the aorta (15%), stenosis at the origin of the subclavian and carotid arteries or renal artery stenosis (5%), very rarely ventricular septal defect. Obstruction of the left main coronary artery origin is more frequent, but it can occur also in the right. In the absence of obstruction at the origin, the coronary arteries are exposed to high pressure and as a consequence they present with dilatations, tortuosities and medial hypertrophy.

**Surgical options**

**Localized type**

*Classical technique:* the aorta is opened above the valve and the incision is prolonged into the right coronary sinus or into the noncoronary sinus or into both the right and noncoronary sinuses. After inspection of the origin of the coronary arteries, the intimal shelf is resected. Aortic enlargement is then obtained with either a diamond-shaped (in the case of a single incision in one of the sinuses of Valsalva) or with an inverted-Y (in the case of incision extending into both the right and noncoronary sinuses) prosthetic patch.

*Brom technique:* the aorta is completely transected just above the supravalvular stenosis, all sinuses of Valsalva are incised and enlarged with three separate prosthetic patches; the ascending aorta is then reconstructed with end-to-end anastomosis.

**Fig. 3.12.5.** Supravalvular aortic stenosis. MRI images: anteroposterior (a) and lateral (b) projections showing moderate to severe degree of supravalvular aortic stenosis, with mild to moderate degree of aortic arch hypoplasia; the aortic wall appears thickened, and this extends around the arch and into the neck vessels. c 3-dimensional contrast-enhanced MRI, lateral view, showing moderate to severe degree of supravalvular aortic stenosis, with mild to moderate degree of aortic arch hypoplasia (photographs courtesy of Dr. Philipp Beerbaum and Dr. Rob Johnson)
Diffuse type: Deep hypothermia and circulatory arrest are generally required. The incision corresponding to the supravalvular obstruction is prolonged through the ascending aorta and aortic arch, until reaching a normal diameter of the aorta. Enlargement is obtained with a prosthetic patch or with an aortic homograft.

Pre-operative information

Especially in patients with Williams's syndrome, CT scan (Fig. 3.12.5 a) and MRI (Figs. 3.12.5 b and 3.12.6) are very helpful to visualize the entire aorta and the peripheral pulmonary arteries. In these cases, in addition to the MRI protocol described above, MR angiography targeted to both the pulmonary and systemic circulation is necessary.
Fig. 3.12.7. Supravalvular aortic stenosis, status post repair. MRI post-operative imaging of the ascending aorta after surgical repair. **a** MR angiography maximal intensity projection reconstruction; **b** fast spin echo imaging in the para-sagittal plane (Asc. aorta ascending aorta, LV left ventricle)

Fig. 3.12.8. Supravalvular aortic stenosis, status-post repair. MRI with post-operative imaging of the ascending aorta after surgical repair of supravalvular aortic stenosis and aortic coarctation. **a** MR angiography maximal intensity projection reconstruction; **b** fast spin echo imaging in the para-sagittal plane (Asc. aorta ascending aorta, LV left ventricle)
Potential complications

Residual or recurrent supravalvular stenosis, aortic valve regurgitation, coronary artery lesion.

Post-operative follow-up

As for the pre-operative investigation, CT scan and MRI (Figs. 3.12.7 and 3.12.8) are very useful to visualize the entire aorta and to show the result of the surgical reconstruction.

References

**Definition**

Aortic coarctation is a congenital narrowing of the aortic lumen, usually situated between the origin of the left subclavian artery proximally and the junction of the aorta and the ductus arteriosus distally. When the coarctation is an isolated finding, the wall of the aorta is pinched in a waist-like fashion, the ascending and descending portions of the arch tending to expand above and below the site of coarctation. The narrowing may consist of an elongated and diffuse tract, proximally to the ductus arteriosus (Fig. 3.13.1), or of a sharp constriction in the area of aortic insertion of the arterial duct, with a diaphragmatic shelf of fibrous tissue protruding into the lumen, often with a pin-hole orifice representing the only communication between the ascending and descending aortic segments (Fig. 3.13.2). Aortic arch hypoplasia of mild or severe degree may also be present (Figs. 3.13.3–3.13.5). Collateral circulation between the aorta proximal and distal to the aortic coarctation increases in size and extensiveness as the patient ages (Fig. 3.13.6).

Occasionally the aorta may be redundant and severely kinked opposite the ligamentum arteriosum, without any pressure gradient or with a mild gradient, so-called pseudo-coarctation (Fig. 3.13.7).

**Associated anomalies**

Patent ductus arteriosus, atrial septal defect, atrioventricular septal defect, ventricular septal defect, double inlet ventricle (with or without actual or potential systemic outlet obstruction), supravalvular or valvular mitral stenosis, valvular or subvalvular aortic stenosis (frequently with bicuspid aortic valve), multiple stenotic lesions of the left heart (= Shone’s syndrome), transposition of the great arteries (usually with ventricular septal defect, with or without actual or potential systemic outlet obstruction), double-outlet right ventricle (usually with ventricular septal defect, with or without actual or potential systemic outlet obstruction), trun-
Fig. 3.13.2. Aortic coarctation. Fast spin echo MRI acquisition showing different types of aortic coarctation: “discrete” shelf (arrow) clearly seen at the isthmus level (a) and an elongate type of aortic coarctation (arrow) (b) (Coa aortic coarctation)

Fig. 3.13.3. Aortic coarctation with hypoplastic aortic arch. CT scan, sagittal projection, contrast angiography showing the diffuse narrowing of the hypoplastic distal transverse aortic arch with severe aortic coarctation (arrow), and the distal systemic circulation perfused by a patent ductus arteriosus (AAo ascending aorta, AoA aortic arch, DTA descending thoracic aorta, PDA patent ductus arteriosus) (photograph courtesy of Dr. Mohamed Tawil)
cus arteriosus, double discordance, hypoplastic left heart, anomalous origin of coronary arteries, anomalous right subclavian artery, intracranial aneurysms, very rarely tetralogy of Fallot.

**Surgical options**

All the following procedures are performed through a left posterolateral thoracotomy without cardiopulmonary bypass. If present, the patent ductus arteriosus is ligated and divided. Occasionally, in adults with complex anatomy or recurrent coarctation, a temporary bypass (from the ascending aorta or from the left atrium to the descending thoracic aorta) may be utilized.

In the case of repair of associated lesions with cardiopulmonary bypass from median sternotomy, the repair of aortic coarctation is performed through a transmediastinal approach.

- **Resection and end-to-end anastomosis:**
  - this is the standard procedure for discrete aortic coarctation,
  - in neonates and infants with aortic arch hypoplasia this can be extended to the aortic arch,
  - in adults, due to poor mobilization of the aortic stumps, conduit interposition may (rarely) be necessary after aortic resection in order to avoid excessive tension of the anastomosis.
Subclavian flap aortoplasty:
- The aortic enlargement is obtained by utilizing the left subclavian artery, opened longitudinally and brought down and sutured to enlarge the aortic isthmus,
- This can be modified in reverse subclavian flap to enlarge a hypoplastic aortic arch.

Patch aortoplasty:
A biological (rarely) or synthetic (frequently) patch is implanted to enlarge the narrow aortic isthmus, opened with a longitudinal incision. However, this technique is nowadays virtually abandoned because of the frequent reports of aneurysm formation in the area of the prosthetic patch. An acceptable alternative option, particularly in infants, is aortoplasty using the enlarged base of the transected left subclavian artery.

Aortic bypass:
Rarely, in case of complex or recurrent coarctation or in case of pseudo-coarctation (aortic kinking, without collateral circulation), a synthetic tubular prosthesis may be inserted between the ascending aorta (through an extended left or a right thoracotomy) or the left subclavian artery (left thoracotomy) and the distal descending thoracic aorta.

Pre-operative information
In infants, transthoracic echocardiography is generally sufficient to correctly diagnose aortic coarctation. However, in children and adults, as the anatomy of the arch can be
difficult to assess by echocardiography (Fig. 3.13.8), CT scan and MRI can provide excellent anatomic details of the aortic arch and are very helpful for the decision-making process to decide between interventional and surgical treatment. The advantages and disadvantages of CT and MRI have already been discussed in the “Introduction”.

The preoperative informations required in suspected aortic coarctation are the following:

- anatomy of the aortic arch and isthmus, including cross-sectional diameters and relationship to brachiocephalic vessels. The aortic arch diameter accepted as normal in neonates and infants is ≥1 mm/kg of body weight; however some consider the aortic arch as hypoplastic if the ratio aortic arch/descending aorta diameter at the level of the diaphragm is <0.9,
- potential associated anomalies: bicuspid aortic valve, patent ductus arteriosus, anomalous right subclavian artery (Fig. 3.13.9),
- severity of the obstruction and hemodynamics,
- left ventricular volume, mass and function.

Classically, the severity of aortic coarctation is evaluated by measuring the pressure gradient as assessed by cardiac catheterization. Echo Doppler can assess the pressure gradient as well, even if some inaccuracies have been reported due to the fact that the utilized mathematical model (Bernoulli) cannot equally fit depending upon the severity of the stenosis. Recently a model using MRI to

**Fig. 3.13.8.** Complex aortic coarctation. MR angiography volume rendering reconstruction in a young adult showing the complex anatomy of native aortic coarctation (a and b) not fully delineate by echocardiography (Ao Arch aortic arch, Asc Ao ascending aorta, Ao Coa aortic coarctation, LCA left carotid artery, LSA left subclavian artery)

**Fig. 3.13.9.** Aortic coarctation with anomalous right subclavian artery. Fast spin echo MRI showing aortic coarctation with anomalous right subclavian artery (Ao Arch aortic arch, Coa aortic coarctation, DA descending thoracic aorta, RSA right subclavian artery)
predict the probability of a hemodynamically significant aortic coarctation pressure gradient (defined as ≥20 mmHg measured during cardiac catheterization) was developed at Boston Children’s Hospital. A combination of the smallest cross-sectional area of the aorta (measured from the gadolinium-enhanced 3-dimensional MR angiography) and the heart rate-adjusted mean deceleration of flow in the descending aorta (measured by PVC-MRI distal to the aortic coarctation) was able to predict a gradient ≥20 mmHg with 95% sensitivity and 82% specificity, 90% positive and negative predictive values. Other investigators performed MRI flow measurements in the ascending and descending aorta distal to the aortic coarctation; compared to controls, patients with aortic coarctation had a significantly lower descending to ascending aorta flow ratio as well as a smaller, more blunted descending aortic flow profile. In aortic coarctation, severe obstruction is suggested by the presence of increased collateral flow; higher collateral flow is expected to decrease the likelihood of spinal cord ischemic injury during surgical treatment involving interruption of aortic blood flow during cross clamping. If little collateral flow is found, the surgeon may consider performing left heart bypass to the descending aorta during the surgical repair.

The following cardiac MRI protocol is used in the evaluation of aortic coarctation:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the “Introduction”),

**Fig. 3.13.10.** Status post repair of aortic coarctation with hypoplastic aortic arch. **a** 3-dimensional reconstruction of a postoperative CT in the same patient of Fig. 3.13.4 with contrast angiography, posterior coronal view, showing the reconstructed aortic arch; the anomalous left subclavian artery has been sacrificed. **b** 3-dimensional reconstruction of a postoperative CT in the same patient of Fig. 3.13.4 with contrast angiography, oblique sagittal projection, showing the reconstructed aortic arch and a pulmonary artery banding (arrows) associated because of the presence of multiple ventricular septal defects (AAo ascending aorta, AoA aortic arch, DTA descending thoracic aorta, LPA left pulmonary artery, MPA main pulmonary artery, RPA right pulmonary artery, RV right ventricle) (photographs courtesy of Dr. Mohamed Tawil)
ECG-gated cine steady-state free precession and static fast spin echo on the parasagittal plane to visualize the aortic arch and the aortic coarctation site. Quite often the arch is distorted in patients with aortic coarctation, so it does not lie on a single plane; thus, additional planes are required to fully delineate the aortic arch and isthmus.

MR angiography volume rendering reconstruction in the same patient of Fig. 3.13.8 showing the tubular prosthesis interposed between the left subclavian artery and the descending thoracic aorta. This technique was chosen to bypass the narrowing due to the adult age and the complex anatomy of the native aortic coarctation (Ao aorta, LSA left subclavian artery)

**Fig. 3.13.12.** Recurrent aortic coarctation. a MR angiography volume rendering reconstruction showing significant aortic re-coarctation. b The flow pattern at the coarctation site shows the typical flow profile of significant aortic coarctation: prolonged deceleration with increased antegrade diastolic flow (Ao Coa aortic coarctation, LCA left carotid artery, LSA left subclavian artery)
gadolinium-enhanced 3-dimensional MRI for the evaluation of the aortic arch and brachiocephalic vessels and collaterals (Fig. 3.13.6).

### Potential complications

Residual or recurrent aortic coarctation, hemorrhage, paraplegia, paradoxical arterial hypertension, abdominal pain, mesentery (necrotising) vasculitis, chylothorax, aneurysm (after patch aortoplasty), left upper arm ischemia (after subclavian flap), recurrent nerve lesion.

### Post-operative follow-up

CT angiography and MRI with 3-dimensional reconstructions represent reliable noninvasive techniques to replace diagnostic cardiac catheterization with angiography in the postoperative follow-up for aortic coarctation and provide valuable information concerning the need for interventional procedures or re-operations without further invasive investigations (Figs. 3.13.10 and 3.13.11).

Fig. 3.13.15. Aortic coarctation, status post balloon dilatation. CT scan in a neonate, contrast angiography, oblique sagittal projection, showing the relatively hypoplastic aortic arch with aortic coarctation (arrow), after successful balloon dilatation of the aortic coarctation (AoA aortic arch, DTA descending thoracic aorta, ETT endotracheal tube, LCA left carotid artery, LSA left subclavian artery, NGT naso-gastric tube, RCA right carotid artery, RSA right subclavian artery) (photograph courtesy of Dr. Mohamed Tawil)

Fig. 3.13.16. Aortic coarctation and anomalous right subclavian artery, status post stent implantation. Aortic coarctation and aberrant subclavian artery in the same patient of Fig. 3.13.9 successfully treated with a stent as illustrated by fast spin echo MRI showing the good position of the stent (a) and the patent right subclavian artery (b) (Ao Arch aortic arch, RSA right subclavian artery)
Both techniques can provide morphometric and morphologic findings such as different aortic diameters, presence of residual or recurrent stenosis (Fig. 3.13.12), aneurysms (Fig. 3.13.13), intimal flaps, circumscribed pouches, and arteriosclerotic plaques. Indication for re-operation after coarctectomy can be established based on the CT or MRI demonstration of residual or recurrent distal aortic arch obstruction, depending also on the aortic arch geometry. Three types of geometry have been described (Fig. 3.13.14):

a) gothic arch with angular geometry and increase height/width ratio,

b) crenel arch with a rectangular shape,

c) normal arch with smooth rounded shape (= Romanesque).

The gothic arch is associated with high risk of hypertension in young adult life.

Localized dilatation of aorta late after repair with patch aortoplasty is primarily due to the use of a large synthetic patch, and partly to increased aortic wall growth. Serial investigations are indicated to monitor the aortic wall growth and the potential occurrence of aneurysm in association with the aortoplasty.

After interventional procedures of balloon dilatation (Fig. 3.13.15) and stenting (Fig. 3.13.16) to treat native or recurrent coarctation, volume-rendered images also may provide valuable insight regarding the endovascular stent position, its relationship to the origin of the great arteries, and potential aortic wall complications, such as aneurysm and dissection.

The MRI protocol is the same as preoperative evaluation. The fast spin echo sequences are particularly useful in case of stent dilatation because they present fewer metallic artifacts.

References

**Chapter 3.14 Aortic arch interruption**

**Definition**

The aortic arch is described as three segments: proximal, distal and isthmus. The proximal component extends from the take-off of the innominate artery to the left common carotid artery. The distal component extends from the left common carotid artery to take-off of the left subclavian artery. The segment of the aorta connecting the distal aortic arch to the juxtaductal region of the descending aorta is termed the isthmus. This complex composite of segments introduces a risk of developmental anomalies in the form of interruptions at the various junction points. Aortic arch interruption is characterized by complete lack of anatomic continuity between the aortic arch or isthmus and the descending thoracic aorta. In aortic arch atresia, with identical pathophysiology and hemodynamics, there is anatomic continuity between the two segments, represented by an imperforate fibrous strand of various lengths. Three anatomic types of aortic arch interruption have been described:

- **Type A**: the interruption is distal to the left subclavian artery.
- **Type B**: the interruption is between the left common carotid artery and the left subclavian artery.
- **Type C**: the interruption is between the innominate artery and the left common carotid artery.

**Associated anomalies**

Patent ductus arteriosus, ventricular septal defect, actual or potential systemic left ventricular outflow tract obstruction, bicuspid aortic valve, double outlet right ventricle, univentricular heart with discordant ventriculoarterial connection, aortopulmonary window, truncus arteriosus, atrial isomerism. Patent ductus arteriosus is always present. The ventricular septal defect is nearly always present, in the majority of cases of malalignment-type, subpulmonic, because of posterior malalignment of the ventricular septum. Subaortic stenosis is also generally present, due to the posterior malalignment of the ventricular septum.

**Surgical options**

Two surgical approaches are available:

- **Two stages**, with repair of the interrupted aortic arch and pulmonary artery banding, followed by later closure of the ventricular septal defect;
- **Single stage**, with simultaneous repair of the interrupted aortic arch and a patch closure of the ventricular septal defect.

In the absence of associated lesions other than patent ductus arteriosus and ventricular septal defect, primary repair by direct anastomosis of the arch with closure of the ventricular septal defect is the preferred surgical approach. The main reason is that pulmonary artery banding might promote or aggravate subaortic stenosis in patients with a malalignment ventricular septal defect. Although the primary repair is physiologically corrective, it should not be viewed as fully curative due to the high incidence of significant late obstruction of the left ventricular outflow tract.
Left ventricular outflow tract obstruction:
The morphology of left ventricular outflow tract obstruction with interrupted aortic arch varies, and therefore, surgical management also varies according to the specific circumstances.

Pre-operative information

CT and MRI investigations (Figs. 3.14.1 and 3.14.2) allow the precise identification of aortic arch interruption type, distance between proximal and distal segments, size of the patent ductus arteriosus, narrowest dimension of the left ventricular outflow tract, and association of other malformations potentially interfering with the surgical planning, such as intracardiac defects, the presence of an anomalous retro-esophageal right subclavian artery, the presence of a right aortic arch.

The cardiac MRI protocol used for the evaluation of infants with aortic arch interruption is the following:
- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the “Introduction”),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of ventricular dimensions, function, mass and stroke volume, as illustrated in the appendix of the “Introduction”,
- ECG-gated cine steady-state free precession sequence to visualize the left ventricular outflow tract and the aortic valve,
- gadolinium-enhanced 3-dimensional MRI for the evaluation of the aortic arch, brachiocephalic arteries and patent ductus arteriosus.

MR angiography showing the aortic arch interruption (arrow), with the distal systemic circulation perfused through a patent ductus arteriosus (AAo ascending aorta, AoA aortic arch, DTA descending thoracic aorta, IA innominate artery, LCA left carotid artery, LSA left subclavian artery, LV left ventricle, PA pulmonary artery, PDA patent ductus arteriosus)
Fig. 3.14.3. Aortic arch interruption: status post repair. CT scan in the same patient of Fig. 3.14.1 with left oblique posterior sagittal view, volume rendering imaging, showing the end-to-side anastomosis (arrow) used to reconstruct the aortic arch continuity one year after surgery (AAo ascending aorta, DTA descending thoracic aorta) (photograph courtesy of Dr. Mohammed Tawil)

Fig. 3.14.4. Aortic arch interruption with ventricular septal defect, status post repair. MRI fast spin echo 3-chamber view parallel to the left ventricular outflow tract. Note the severe subaortic stenosis due to posterior infundibular deviation (arrow) (ao aorta, LV left ventricle)

Fig. 3.14.5. Aortic arch interruption, status post surgery with direct anastomosis. MR angiography maximal intensity projection reconstruction (a) and volume rendering reconstruction (b) showing normal brachiocephalic arteries and significant aortic isthmus narrowing (Ao Arch aortic arch, Desc Ao descending thoracic aorta, LSA left subclavian artery)
Potential complications

Residual pressure gradient at the level of the aortic arch anastomosis and/or at the left ventricular outflow tract, residual ventricular septal defect, complete atroventricular block, left bronchial obstruction.

Left bronchial obstruction: The left main bronchus passes under the aortic arch. If a direct anastomosis is performed without adequate mobilization of the ascending and descending aorta, a bowstring effect over the left main bronchus may result. This is manifested by air trapping in the left lung with hyperexpansion, as seen on chest radiography and confirmed by bronchoscopy. Surgical management may require an ascending-to-descending aortic conduit after division of the arch.

Post-operative follow-up

The role of CT scan (Fig. 3.14.3) and MRI after surgery for aortic arch interruption is to evaluate residual or recurrent anatomic and hemodynamic problems, such as aortic arch obstruction or aneurysm formation. However, other abnormalities (e.g., left ventricular outflow tract obstruction, aortic valve stenosis or regurgitation, residual ventricular septal defect, left ventricular size and function) should be examined as well. CT scan and MRI are also useful in case of suspected post-operative left bronchial compression.

The following protocol is suggested in the post-operative evaluation of patients with arch interruption:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the “Introduction”),
- ECG-gated cine steady-state free precession and fast spin echo para-sagittal,

![Fig. 3.14.6. Truncus arteriosus and aortic arch interruption, status post repair. MR angiography MIP reconstruction (a) and volume rendering reconstruction (b) showing an aortic arch aneurysm, mild ascending aorta stenosis and significant aortic isthmus obstruction (Asc Ao ascending aorta, Ao arch aortic arch, Ao root aortic root, Desc Ao descending thoracic aorta, LA left atrium)](image-url)
coronal and additional oblique plane (if needed) to visualize the aortic arch,
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of ventricular dimensions, function, mass and stroke volume as illustrated in the appendix of the “Introduction”,
- ECG-gated cine steady-state free precession and fast spin echo sequence parallel to the left ventricular outflow tract (Fig. 3.14.4),
- ECG-gated phase velocity contrast (PVC-MRI) sequences perpendicular to the ascending aorta, aortic arch, isthmus, proximal and distal descending aorta. Additional flow measurements, based on clinical relevance, such as assessment of potential aortic valve regurgitation or to quantitate the intracardiac shunt in case of suspected residual ventricular septal defect, are sometime required as well,
- gadolinium-enhanced 3-dimensional MRI for the evaluation of the aortic arch and brachiocephalic arteries (Figs. 3.14.5 and 3.14.6).

Definition

Transposition of the great arteries is an abnormality of ventriculoarterial connection, with the aorta originating from the morphologically right ventricle and the pulmonary artery from the morphologically left ventricle. The aorta is anterior and slightly to the right of the main pulmonary artery. The aortic valve is to the right of the pulmonary valve but still anterior to it. The main pulmonary artery is in a position, with respect to the left ventricle, such that there is direct flow into the right pulmonary artery; as a consequence the right pulmonary artery becomes larger, with more flow to the right lung.

There are four major subgroups of complete transposition of the great arteries:

- **Transposition of the great arteries with intact ventricular septum or with restrictive ventricular septal defect (60% of the cases):** one-third of patients with complete transposition of the great arteries and ventricular septal defect will have closure of the ventricular septal defect in the first year of life.

- **Transposition of the great arteries with unrestricted ventricular septal defect (20%):** the most common position of ventricular septal defects in transposition of the great arteries is the infundibular septum, with or without malalignment, followed by defects in the membranous septum.

- **Transposition of the great arteries with ventricular septal defect and left ventricular outflow tract obstruction (15%):** pulmonary stenosis (left ventricular outflow tract obstruction) in patients with transposition of the great arteries is due to the leftward bowing of the ventricular septum due to the elevated (systemic) right ventricular pressure, and to the close proximity of the mitral valve to the ventricular septum, leading to dynamic obstruction. Anatomical valvular and subvalvular pulmonary stenoses are more rare, and mainly due to tissue tags, aneurysm of the membranous septum, straddling of the atrioventricular valve, pulmonary valve stenosis.

- **Transposition of the great arteries with intact ventricular septum and left ventricular outflow tract obstruction (5%):** most infants with complete transposition of the great arteries have patent foramen ovale and a patent ductus arteriosus.

Coronary arteries: In 60% of patients, the right coronary artery originates from the right coronary sinus and the left coronary artery, whereby the circumflex and left anterior descending arteries originate from the left coronary sinus. In 10% of patients, the right coronary artery and the circumflex originate from the right coronary sinus with the left anterior descending artery originating from the left coronary sinus. In these cases the circumflex is located posterior to the pulmonary artery. In another 10% of patients, the circumflex originates from the right coronary sinus, and the right coronary artery and left anterior descending artery originate from the left coronary sinus. In these cases the right coronary artery is located rightwards anterior to the aorta. In an-
other 10% of patients, the right coronary artery originates from the right coronary sinus and gives origin to the right coronary artery and the left coronary artery; in these cases the left coronary artery is located between the aorta and the pulmonary artery and gives origin to the circumflex and the left anterior descending branches. In 5% of patients, there is a single origin of all the coronary arteries, either from the right or from the left sinus, and this anomaly can complicate the surgical technique of arterial switch. The most troublesome coronary anomaly in view of arterial switch is an intramural coronary artery (3–5%): in this situation the first portion of a coronary artery, generally the left, is located within the aortic wall, before assuming epicardial distribution.

Associated anomalies

Right aortic arch is seen in 4% of patients with an intact ventricular septum and in 8% of patients with a ventricular septal defect. A right aortic arch is more common (10%) in patients with transposition of the great arteries with pulmonary stenosis or pulmonary atresia. Other associated anomalies include the following: aortic coarctation (5%), left juxtaposition of the auricular appendages (2–4%), malformations of the tricuspid (including Ebstein’s anomaly) or the mitral valve, right or left ventricular hypoplasia, superoinferior ventricles, subaortic stenosis.

Surgical options

Atrioseptectomy: The original procedure of atrioseptectomy (Blalock-Hanlon) is nowadays virtually abandoned, replaced by balloon atrioseptostomy (Rashkind) performed with venous access by the interventional cardiologists.

Atrial rerouting: Mustard procedure and Senning procedure: In these two different surgical techniques of intraatrial rerouting, the oxygenated blood of the pulmonary venous returns is channeled towards the tricuspid valve, and therefore to the right ventricle and the aorta, while the desaturated blood of the systemic venous returns is channeled towards the mitral valve, and therefore to the left ventricle and the pulmonary artery.

Arterial switch (Jatene operation): The aorta and pulmonary artery are divided above the sinuses. The coronary arteries are excised from the aortic root with a button of aorta and implanted in the new aortic root (old pulmonary artery). The pulmonary artery bifurcation is brought anterior to the aorta (Lecompte maneuver) and the ascending aorta is anastomosed to the new aortic root. A portion of pericardium is utilized to close the defects created in the neopulmonary root (old aorta) by the excision of the coronary arteries, and the pulmonary artery bifurcation is anastomosed to the new pulmonary artery root.

Rastelli operation: After right ventriculotomy, the ventricular septal defect is closed with a prosthetic patch (generally PTFE) by creating a tunnel which connects the left ventricle to the aorta, and continuity between the right ventricle and the pulmonary artery is obtained with a biological valved conduit.

Lecompte procedure (or REV = Réparation à l’Etage Ventriculaire): After right ventriculotomy and infundibular resection, the left ventricle is connected to the aorta by closure of the ventricular septal defect with a straight patch. After transection and shortening of the ascending aorta and transfer of the pulmonary artery bifurcation anterior to the aorta (Lecompte maneuver), the right ventricle-to-pulmonary artery continuity is obtained with reimplantation of the transacted pulmonary artery directly on the right ventricle for its posterior wall, while the anterior aspect is connected to the rest of the right ventriculotomy with a monocusp pericardial patch.
### Damus-Kaye-Stansel procedure:

The pulmonary artery is transected proximal to the bifurcation and end-to-side anastomosed to the ascending aorta, diverting the left ventricular outflow to the systemic circulation; the ventricular septal defect is closed with a prosthetic patch. The continuity between the right ventricle and the pulmonary artery is obtained with a biological valved conduit implanted between the right ventriculotomy and the pulmonary artery bifurcation.

### Bex-Nikaidoh procedure (aortic translocation):

The aortic root is completely harvested, with or without excision of the coronary arteries, as well as the pulmonary valve. After the incision of the infundibular septum and the transfer of the pulmonary artery bifurcation anterior to the aorta (Lecompte maneuver), the aortic root is connected to the posterior left ventricle, with or without reimplantation of the buttons of the excised coronary arteries, closing the ventricular septal defect at the same time. The pulmonary artery is then connected to the anterior right ventricle.

### Pre-operative information

The diagnostic criterion of complete transposition of the great arteries is the presence of a discordant ventriculoarterial connection (Fig. 3.15.1). Detailed images of the spatial relationship between the two great arteries and their size discrepancy, the presence of associated malformations, in particular a ventricular septal defect and left ventricular outflow tract obstruction, as well as origin and course of the coronary arteries, are crucial insights for the decision-making process among the various available surgical options.

In the presence of systemic obstructions, particularly aortic coarctation with hypoplastic aortic arch or aortic arch interruption, a more accurate representation of the morphology of the great arteries is required for better surgical planning. In case of indication for atrial re-routing (Mustard or Senning), it is also mandatory to assess the morphology and position of the auricular appendages (Fig. 3.15.2). In case of complete transposition of the great arteries with intact ventricular septum, an arterial switch is feasible only in the first few weeks of life. For later referral, it is crucial to estimate the left ventricular mass in order to evaluate the possibility of the morphologic left ventricle to function as the systemic ventricle after an arterial switch operation. In patients with ventricular septal defect and left ventricular outflow tract obstruction, a detailed definition of the intracardiac anatomy is useful to decide between the available options: Rastelli, Lecompte (REV) or Bex-Nikaidoh procedures. In all the above situations, echocardiography and cardiac catheterization with angiography can provide most of the required information. However, in some complex cases, more sophisticated imaging tools could provide some anatomical details that
are not available with traditional diagnostic investigations. Particularly attractive is the development of a stereolithographic model derived from a standard CT scan or MRI to create accurate and realistic models of complex congenital defects for pre-operative assessment and intraoperative orientation; a virtual incision-making tool that allows arbitrary incisions to be made in a 3-dimensional reconstruction of the MRI data has been developed.

In summary, CT scan and MRI are seldom required for pre-operative assessment of infants with transposition of the great arteries. However the development of new acquisition and MRI techniques able to display high-resolution 3-dimensional heart images, ready to be post-processed, could greatly help surgeons planning surgical repair particularly in the case of intraventricular rerouting.

**Potential complications**

- **Atrioseptostomy/atrioseptectomy**: supraventricular arrhythmias, inadequate mixing at the atrial level,
- **Atrial rerouting**: arrhythmias, tricuspid valve regurgitation, right (systemic) ventricular dysfunction, residual or recurrent obstruction of the pulmonary or the systemic venous return because of stenosis of the new caval or pulmonary venous channels,
- **Arterial switch (Jatene operation)**: residual or recurrent coronary arteries stenosis because of the coronary artery reimplantation, residual or recurrent obstruction of the new right ventricular outflow tract (more frequent) or the new left ventricular outflow tract (much more rare), aortic valve regurgitation,
- **Rastelli operation**: residual or recurrent ventricular septal defect, residual or recurrent obstruction of the new left ventricular outflow tract, obstruction of the right ventricle-to-pulmonary artery valved conduit, complete atrioventricular block,
- **Lecompte procedure (or REV = Réparation à l’Etage Ventriculaire)**: residual or recurrent ventricular septal defect, residual or recurrent obstruction of the new right ventricle outflow tract, complete atrioventricular block, pulmonary artery stenosis due to pulmonary arteries stretching,
- **Damus-Kaye-Stansel procedure**: residual or recurrent ventricular septal defect, residual or recurrent obstruction of the new left ventricular outflow tract, late regurgitation of the systemic (aortic or pulmonary) valves, obstruction of the right ventricle-

MRI 2-dimensional time of flight volume rendering reconstruction (a), and maximal intensity projection reconstruction (b) showing significant baffle obstruction of the superior vena cava (IVC inferior vena cava, LV left ventricle, SVC superior vena cava)

Fig. 3.15.5. Transposition of the great arteries, ventricular septal defect and pulmonary stenosis, status post Rastelli procedure. MR angiography maximal intensity projection reconstruction (a) and volume rendering reconstruction (b) showing a stenosis of the pulmonary homograft. Note the anterior location of the pulmonary artery bifurcation because of the Lecompte maneuver (Pulm pulmonary, RV right ventricle)
Post-operative follow-up

In the post-operative evaluation of patients with transposition of the great arteries, cardiac MRI is assuming an increasing role due to its ability to noninvasively evaluate most clinically relevant issues. The goals of evaluation of post-operative atrial switch (Mustard or Senning) include:

- quantitative evaluation of the size and function of the systemic right ventricle (Fig. 3.15.3),
- imaging of the systemic and pulmonary venous pathways to rule out obstructions and/or baffle leaks (Fig. 3.15.4),
- assessment of tricuspid (systemic) valve regurgitation,
- evaluation of the left and right ventricular outflow tracts,
- detection of aortopulmonary collateral arteries and other associated anomalies.

In patients with right (systemic) ventricular dysfunction, post-gadolinium delayed myocardial enhancement can be used to detect myocardial fibrosis. The response of the systemic right ventricle to pharmacological stress (dobutamine) or to exercise can be tested by cardiac MRI. However, the clinical utility of these informations requires further studies.

The long-term follow-up of patients after arterial switch, Rastelli, Lecompte (REV) or Bex-Nikaidoh procedures mainly focuses on the technical challenges of each of the above mentioned operations: transfer of the coronary arteries from the native aortic root to the neoaortic root (native pulmonary root); transfer of the pulmonary arteries anterior to the neoascending aorta; reconstruction of the right and left ventricular outflow tracts.

**Fig. 3.15.6.** Transposition of the great arteries, status post arterial switch. MR angiography maximal intensity projection reconstruction (a) and volume rendering reconstruction (b and c) showing pulmonary stenosis due to the compression between the aorta and the sternum (AO aorta, LPA left pulmonary artery, MPA main pulmonary artery, RPA right pulmonary artery, RV right ventricle).
Fig. 3.15.7. Transposition of the great arteries, status post arterial switch. **a** MR angiography showing the post-operative images after arterial switch. **b** Different projection with the main pulmonary artery and the origin of the two branches compressed and displaced by the new ascending aorta (Ao aorta, LV left ventricle, PA pulmonary artery, RV right ventricle)

Fig. 3.15.8. Transposition of the great arteries, status post arterial switch. Left ventricular outflow tract steady-state free precession cine MRI (**a**) and fast spin echo parasagittal view (**b**) showing a dilated aortic root leading to a significant aortic valve regurgitation (regurgitation fraction calculated by PVC-MRI = 40%). Note in steady-state free precession (**c**) and FSE (**d**) aortic valve short-axis acquisition with the lack of coaptation of the leaflets (AO aorta, LCS left coronary sinus, LV left ventricle, MPA main pulmonary artery, RCS right coronary sinus)
Therefore the goals of the post-operative evaluation in these cases include:
- evaluation of global and regional left and right ventricular size and function,
- evaluation of the left and right ventricular outflow tracts (Fig. 3.15.5),
- qualitative estimation of the right systolic pressure based on the configuration of the interventricular septum,
- evaluation of the pulmonary arteries to rule out the presence of stenosis (Figs. 3.15.6 and 3.15.7),
- evaluation of the aortic root and coronary origin (Fig. 3.15.8 and 3.15.9),
- other associated anomalies.

The role of myocardial perfusion and viability imaging in this population deserves further studies.

The above objectives can be achieved by the following cardiac MRI protocol:
- 3-plane localizing images,
- 2-dimensional axial time of flight (see appendix in the “Introduction”),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume as illustrated in the appendix of the “Introduction”,
- ECG-gated cine steady-state free precession and fast spin echo (if needed) sequence to visualize the left ventricular outflow tract and the aortic arch,

**Fig. 3.15.9.** Transposition of the great arteries, status post arterial switch. MRI 3-dimensional steady state free precession volume rendering reconstruction (a) and maximal intensity projection reconstruction (b) showing a suspected mild “kinking” at the origin of the left coronary artery; 3-dimensional steady state free precession volume rendering reconstruction (c) in another patient: no coronary artery stenosis is detected (AO aorta, LCA left coronary artery, LPA left pulmonary artery, RCA right coronary artery)
ECG-gated cine steady-state free precession and fast spin echo short axis (if needed) sequences for the aortic root,
ECG-gated cine steady-state free precession sequence, generally on the sagittal plane, to visualize the right ventricular outflow tract,
ECG-gated cine steady-state free precession sequence to visualize the intraatrial baffles in case of atrial switch,
gadolinium-enhanced 3-dimensional MR angiography,
ECG-gated static 3-dimensional steady-state free precession for the evaluation of origin and proximal course of coronary arteries (Fig. 3.15.9),
ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending aorta and pulmonary arteries, to assess aortic and pulmonary valve regurgitation and pulmonary blood flow,
post-gadolinium delayed myocardial enhancement may be used to evaluate the presence of fibrotic tissue.

Imaging of the coronary arteries and pharmaco-mechanical stress testing (either adenosine or dobutamine) for evaluation respectively of coronary proximal stenosis and myocardial ischemia are increasingly being incorporated into the clinical imaging protocol in the post-operative evaluation of patients with transposition of the great arteries.

Raman SV, Cook SC, McCarthy B, Ferketich AK (2005) Usefulness of multidetector row computed tomography to quantify right ventricular size and function in adults with either tetralogy of Fallot or transposition of the great arteries. Am J Cardiol 95:683–686

**Definition**

The morphological features of the hypoplastic left heart syndrome are:
- mitral atresia or severe stenosis
- aortic atresia or severe stenosis
- left ventricular hypoplasia or aplasia
- left atrial hypoplasia
- interatrial communication
- patent ductus arteriosus
- aortic coarctation
- right atrial dilatation
- right ventricular dilatation and hypertrophy

The apex is formed by the right ventricle and the epicardial course of the left anterior descending coronary artery defines a very small or non-existent left ventricle. The ascending aorta may be as small as 1 or 2 mm, but enough to supply blood to the coronary arteries in a retrograde fashion from the patent ductus arteriosus. A patent foramen ovale is generally small, with herniation of the valve of the septum primum from left-to-right, or even closed. Premature closure of the patent foramen ovale is usually accompanied by severe hypoplasia of the left heart cavities. Endocardial fibroelastosis can be also present. Connections of the left ventricle to the coronary arteries have been described. The ductus arteriosus is widely patent, serving as a downward-directed conduit from the main pulmonary artery to the descending thoracic aorta. The neonates are generally not born with aortic coarctation, but it frequently develops (80% of cases). Obstructions at the level of the aortic arch are frequently present.

**Associated anomalies**

Dextrocardia and isomerism are uncommon, as well as juxtaposition of the auricular appendages. Rare is the incidence of an associated partial anomalous pulmonary venous connection. Aortic arch interruption is very rare. Association with the dominant right form of atrioventricular septal defect, double outlet right ventricle or aortic-left ventricular tunnel are possible. Morphological anomalies of the tricuspid valve are unusual, despite a not infrequent presence of tricuspid valve regurgitation. Extremely rare is the association with pulmonary valve stenosis. Extremely rare is the presence of a ventricular septal defect.

**Surgical options**

Surgical management includes different options:
- **palliation**: stent of the ductus arteriosus and bilateral pulmonary artery banding,
- **univentricular type of repair in three stages**: the first stage is the Norwood procedure, followed by a bidirectional Glenn (end-to-side anastomosis of the superior vena cava to the right pulmonary artery) and then by a modified Fontan procedure (total cavo-pulmonary connection by extracardiac or intracardiac connection of the inferior vena cava to the pulmonary artery),
- **heart transplantation**
Stent of the ductus arteriosus and bilateral pulmonary artery banding: This palliative approach, consisting of stenting the ductus arteriosus to maintain the patency and surgical (or intravascular) bilateral pulmonary artery banding to maintain adequate systemic perfusion through the ductus arteriosus, has been recently proposed with two potential targets:

- to improve the clinical condition of the neonate, particularly if the clinical condition is very critical, to increase the chances of tolerating a subsequent Norwood type of procedure,
- to allow for a stabilization lasting a period long enough to allow for the availability of a donor heart for heart transplantation.

Norwood procedure: the Norwood procedure consists of an initial palliative procedure (first stage) in view of a univentricular type of repair. Palliation includes using the pulmonary valve and proximal main pulmonary artery as the neoaorta, by transecting the distal main pulmonary artery and connecting the proximal main pulmonary artery to the aortic arch and ascending aorta. Then the pulmonary blood flow is provided by a systemic-to-pulmonary artery shunt from the right subclavian artery or the innominate artery to the right pulmonary artery. In addition, the atrial septum is removed surgically to create an unrestricted interatrial communication and the patent ductus arteriosus is divided. Even in the absence of evident aortic coarctation, the area of the aortic isthmus can be bypassed by an aortic homograft to avoid the risk of recurrent aortic coarctation.

Norwood procedure with the Sano variation: the modified Norwood operation, proposed by Sano and nowadays widely adopted, including Norwood himself, replaces the modified Blalock-Taussig shunt with a tubular prosthesis implanted between the anterior aspect of the right ventricle and the pulmonary artery bifurcation. The advantage is to avoid the coronary artery steel of blood during diastole from the systemic-to-pulmonary shunt, difficult to manage after the classical Norwood procedure.

Heart transplantation: Heart transplantation in a hypoplastic left heart is not different from routine heart transplantation, with two exceptions: a) the need of a special technique for cardiopulmonary bypass, due to the presence of ductal dependency of the systemic perfusion; b) the need for reconstruction of the aortic arch and aortic isthmus.

Pre-operative information

Neonatal diagnosis and pre-operative assessment of hypoplastic left heart syndrome is classically performed by echocardiography. CT scan (Fig. 3.16.1) and MRI (Fig. 3.16.2) are very rarely utilized in the preoperative screening.

Potential complications

Norwood procedure: the immediate post-operative period is complicated by the very delicate balance between the systemic and
pulmonary circulation, in parallel with a single ventricle physiology. Tricuspid regurgitation may develop and become progressive, and this represents a major issue since the right ventricle is functioning as the systemic ventricle. Recurrent aortic coarctation is possible in case of incomplete resection of residual ductal tissue. Rarely the pulmonary veins may develop progressive stenosis, and the etiology is unclear.

Norwood procedure with the Sano variation: the main problem reported after the modified technique consists in hypoxia, more evident than after the classic Norwood procedure. Concern remains about long-term effects on ventricular function, because of the ventriculotomy performed on the systemic ventricle (Fig. 3.16.3).

Post-operative follow-up

After the first stage of the Norwood procedure and before the second stage (bidirectional Glenn), the following targets need to be investigated:
- size of the interatrial septal defect,
- systemic ventricular function and myocardial viability,
- systemic atrioventricular (tricuspid) valve function,
- left ventricular outflow tract and systemic semilunar valve,
- morphology of the aortic arch,

![Fig. 3.16.2. Hypoplastic left heart syndrome. Steady state free precession cine MRI 4-chamber (a) and short-axis (b) view in a 3-year-old patient with an indexed end-diastolic left ventricular volume of 21 ml/m² (LV left ventricle, RV right ventricle)
systemic-to-pulmonary shunt (or right ventricle to pulmonary artery conduit in case of previous Norwood with Sano variation),

- morphology, flow and resistance of the pulmonary arteries.

The above information was traditionally obtained by echocardiography and cardiac catheterization with angiography. However if pulmonary vascular resistance is not thought to be elevated and CT (Fig. 3.16.4) and/or MRI (Fig. 3.16.5) are able to address all the issues mentioned above, cardiac catheterization can even be avoided. Furthermore, due to MRI’s capability to detect myocardial scarring and some other important insights (e.g., biventricular volume), MRI has become a very useful tool in borderline cases where conversion to a biventricular type of repair could still be a suitable option.

The following cardiac MRI protocol is proposed in the evaluation of hypoplastic left heart syndrome after the first stage of the Norwood procedure:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the “Introduction”),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of ventricular dimensions, function, mass and stroke volume as illustrated in the appendix of the “Introduction”,
- ECG-gated cine steady-state free precession sequence to visualize the systemic ventricular outflow tract and the neo-aorta (Fig. 3.16.6),
- ECG-gated cine steady-state free precession and, if needed, fast spin echo sequence to visualize the aortic arch and the native neoaorta anastomosis (Fig. 3.16.7),
- ECG-gated cine steady-state free precession and, if needed, fast spin echo sequence to visualize the right ventricle to pulmonary artery conduit (in case of Norwood with Sano variation) and the pulmonary artery branches (Fig. 3.16.8),
- ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending neo- and native aorta, pulmonary arteries, superior vena cava and inferior vena cava to assess the flow pattern,

Postoperative follow-up

Cor triatriatum

I Definition

When used in isolation, the term cor triatriatum almost always refers to division of the left atrium. The divided right atrium is called cor triatriatum dexter.

Several patterns exist in which the left atrial chamber is divided, often in association with anomalous venous connections or other lesions. In the great majority of cases, nonetheless, there is a pattern which can be considered as the “classic” lesion. In this variant, the left atrium is divided by a diaphragm (membrane) into two components: 1) the proximal (superior) left atrial chamber, typically thick-walled, somewhat larger than the distal chamber, above the subdividing diaphragm, receiving the four pulmonary veins; 2) the distal (inferior) left atrial chamber, generally thin-walled, with the opening of the fossa ovalis, the left auricular appendage and the mitral valve. The diaphragm between the two components, which may have one or more variably sized openings in it, is usually rather thick and fibromuscular. Typically, the foramen ovale (which may be deficient, probe-patent or intact) is in actual or potential communication with the distal chamber, and the left auricular appendage is located in the distal chamber; these two features provide a means to distinguish between cor triatriatum and supravalvular mitral ring (see the chapter “Mitral valve disease”). The severity of the lesion depends upon the size of the orifice between the divided components of the left atrium.

Associated anomalies

Cor triatriatum is seen most frequently as an isolated lesion but it can coexist with any other defect. Notable associations include persistent left superior vena cava and unroofed coronary sinus. Other associated lesions can be supravalvular mitral ring, atrial septal defect, partial or total anomalous pulmonary venous connection, stenosis of the pulmonary veins, atioventricular septal defect, mitral valve regurgitation, ventricular septal defect, tetralogy of Fallot, double outlet right ventricle, double discordance, hypoplastic left heart syndrome, aortic valve stenosis, pulmonary stenosis, anomalous origin of the right pulmonary artery from the aorta, aortic coarctation; rarely asplenia or polysplenia.

Surgical options

Complete resection of the diaphragm, taking care not to injure the mitral valve or the interatrial septum, is approached from the left atrium or from the right atrium (through an already present or a surgically created interatrial communication), depending on the size of the proximal left atrial chamber and on the presence of associated anomalies.

In the classical form of cor triatriatum, the surgical approach through a right atriotomy is recommended, with enlargement of the patent foramen ovale (or interatrial septal defect) to obtain better exposure of the left atrial diaphragm. After identification and complete resection of the diaphragm, the remaining interatrial communication is
closed with an autologous (or heterologous) pericardial patch. 

In the left atrial approach, the common pulmonary venous proximal chamber is opened through a vertical incision anterior to the pulmonary veins, and the diaphragm is exposed by appropriate retraction; one or two radial incisions from the opening of the diaphragm outward to the atrial wall or interatrial septum substantially enhance the exposure; the diaphragm is excised only after precise identification of the pulmonary veins.

### Pre-operative information

In addition to the information already obtained with echocardiography, CT scan and MRI can provide details useful to precisely localize the fibromuscular diaphragm (membrane), its relationship with the interatrial septum, the position and the size of its opening connecting the proximal (superior) with the distal (inferior) left atrial chamber, the pulmonary venous connections as well as the presence of associated intracardiac defects (Fig. 3.17.1).

MRI in particular axial and coronal fast spin echo sequences can delineated very well the morphology of the left atrial chamber with the fibromuscular diaphragm (membrane) and its relationship to the near cardiovascular structures. Furthermore, the visualization of a normal left auricular appendage, with a signal void indicating unobstructed flow, excludes other related intracardiac malformations, such as congenital mitral stenosis or supravalvular mitral ring.

![Fig. 3.17.1. Cor triatriatum.](image)

**a** MRI axial projection showing the pulmonary veins (arrow) connected to the proximal (superior) left atrial chamber, the distal (inferior) left atrial chamber emptying through the mitral valve into the left ventricle, and the attachment to the interatrial septum (asterisk) of the fibromuscular diaphragm (membrane) dividing the left atrium. Note the presence of a ventricular septal defect. **b** MRI axial projection in the same patient showing the absence of atrial septal defect, the central opening of the fibromuscular diaphragm (membrane) and its lateral insertion (black arrow) (CI inferior chamber, CS superior chamber, DS ventricular septal defect, LV left ventricle, M mitral valve, RA right atrium, RV right ventricle) (modified with permission from Cabrera A, Angulo P, Martinez P, Romero C, Pastor E, Galdeano JM (1997) Cor triatriatum with interventricular communication: Doppler color ultrasonography and magnetic resonance diagnosis. Repair in the first months. Rev Esp Cardiol 50:290–292, © Elsevier)
Potential complications

Inadequate membrane resection, residual atrial septal defect, mitral valve damage, air embolism, supraventricular arrhythmias; in neonates and infants post-operative crises of pulmonary hypertension requiring treatment are frequent. Pulmonary vein stenosis or restenosis in association with the orifice between the proximal and distal left atrial chambers, generally due to incomplete resection, are quite rare.

Post-operative follow-up

Both CT scan and MRI in the post-operative period can investigate the pulmonary veins and confirm the adequacy of the surgical repair (Fig. 3.17.2) or can show the presence of a residual segment of unresected fibromuscular diaphragm (membrane) or even other residual intracardiac defects.

Definition

Tricuspid atresia is characterized by the complete absence of a direct communication between the right atrium and the right ventricle (= absent right atrioventricular connection). Tricuspid atresia may range from an imperforate membrane (rarely) to the total absence of the valve with the area replaced by muscular tissue. The floor of the right atrium is completely muscular, frequently with a tiny dimple (= localized fibrous thickening) in the middle, and is totally separated from the ventricular mass by the atrioventricular sulcus (= absent of any potential right atrioventricular connection). The right atrium is generally dilated, and its wall thickened, particularly in the rare (less than 5% of cases) presence of restrictive interatrial communication (generally the interatrial communication is unrestrictive). The left atrium and the mitral valve are both dilated, since they receive both the pulmonary and the systemic venous returns. The right ventricle is generally poorly developed (sometimes so small that its detection is difficult) and is characterized by total absence of the inlet portion and varying degrees of underdevelopment of the trabecular and infundibular portions. A ventricular septal defect, most frequently of muscular type, is generally present between the hypoplastic right ventricle and the left ventricle, providing access to the rudimentary right ventricle and the pulmonary artery. The atrial situs is almost invariably solitus, and the coronary arteries are generally normal.

Classification

The classification of the various forms of tricuspid atresia is based on the type of ventriculoarterial connection and on the amount of antegrade pulmonary blood flow.

Type of ventriculoarterial connection

- type I: normally related great arteries (= ventriculoarterial concordance) (2/3 of infants),
- type II: transposition of the great arteries (= ventriculoarterial discordance) (1/3 of infants).

Amount of antegrade pulmonary blood flow

- type A: absence or severe reduction of antegrade pulmonary blood flow, because of pulmonary atresia or stenosis with absent ventricular septal defect (18% of infants); the pulmonary circulation can be totally ductus-dependent,
- type B: balanced antegrade pulmonary blood flow (52% of infants), resulting from a moderate degree of obstruction at the level of the ventricular septal defect, the right ventricular outflow tract and/or the pulmonary valve, bicuspid in 20% of patients,
- type C: unrestricted antegrade pulmonary blood flow (30% of infants), resulting from absence or minimal degree of obstruction at the level of the ventricular septal defect, the right ventricular outflow tract and/or the pulmonary valve.
Associated anomalies

Systemic and pulmonary venous connections are usually normal, with the exception of a persistent left superior vena cava (15% of cases), and partially unroofed coronary sinus with communication between the coronary sinus and the left atrium (1–5% of cases). An atrial septal defect or stretched patent foramen ovale is generally present (the presence of an interatrial communication is necessary for survival) and ventricular septal defect is very frequently present. Ventriculoarterial discordance is present in 1/3 of the patients.

Other associated cardiac anomalies are pulmonary stenosis, pulmonary atresia, patent ductus arteriosus, juxtaposition of the auricular appendages (10% of cases with ventriculoarterial discordance), dextrocardia, right aortic arch, aortic coarctation (very rare in patients with ventriculoarterial concordance, but present in up to 30% of patients with ventriculoarterial discordance and restrictive ventricular septal defect).

In 5% of patients there is a very large prominent Eustachian valve, partitioning the right atrium, like in cor triatriatum dexter (see chapter “Cor triatriatum”). Anecdotal reports exist of tricuspid atresia with anomalous systemic or pulmonary venous connections, aortic atresia and truncus arteriosus. Situs inversus with ventricular L-loop (mirror imaging pattern) is exceptional. The mitral valve, generally normal, may have a double orifice, isolated anterior cleft or straddling and overriding.

Surgical options

- **Modified Blalock-Taussig shunt**: see chapter “Tetralogy of Fallot”.
- **Pulmonary artery banding**: see chapter “Ventricular septal defect”.
- **Bidirectional Glenn or Hemi-Fontan**: see chapter “Single ventricle”.
- **Modified Fontan procedure or total cavopulmonary connection**: see chapter “Single ventricle”.
- **One-and-half ventricular repair**: this surgical approach consists of the confection of a bidirectional Glenn: end-to-side anastomosis between the proximal stump of the superior vena cava divided at the level of the cavoatrial junction and the upper aspect of the right pulmonary artery. The atrial and ventricular septal defects approached through a right atriotomy and a longitudinal incision of the subpulmonary chamber, respectively, are closed with separated patches (pericardium, PTFE, Dacron or Teflon), and then the right atrium is connected with the subpulmonary chamber with interposition of a valved conduit. In the presence of associated pulmonary valve stenosis, a pulmonary valvotomy is required. In the presence of hypoplastic pulmonary valve annulus, the incision of the subpulmonary chamber is prolonged becoming a transannular opening, and the distal end of the conduit is anastomosed to both the subpulmonary chamber and the wall of the pulmonary artery.
- **Subaortic resection**: the technique consists of a longitudinal incision of the subaortic right ventricular outlet chamber in the direction of the ascending aorta, of course avoiding major coronary artery branches. After careful identification of the ventricular septal defect (=bulboventricular foramen), a full-thickness of interventricular septum is resected from the anterosuperior aspect of the defect, on the opposite side of the conduction tissue, carefully avoiding lesions to the adjacent aortic valve. Subaortic resection is completed with excision of obstructing muscle bundles, and the outlet chamber is further enlarged by patch (autologous or heterologous pericardium, PTFE) closure of the incision.
Fig. 3.18.1. Tricuspid atresia. CT scan axial projection showing absence of a direct connection (arrowheads) between the right atrium and the right ventricle (RA right atrium, RV right ventricle)

Fig. 3.18.2. Tricuspid atresia. Typical MRI aspect of tricuspid atresia with nearly virtual accessory chamber (AC accessory chamber, LA left atrium, LV left ventricle)

Fig. 3.18.3. Tricuspid atresia, restrictive ventricular septal defect and ventriculoarterial discordance. Cine MRI left ventricular outflow tract (a and b) showing the aorta arising from the hypoplastic right ventricle with restrictive ventricular septal defect (*) (Ao aorta, LV left ventricle)
Pre-operative information

The pre-operative information is the same as acquired from CT scan (Fig. 3.18.1) and MRI (Fig. 3.18.2) for the evaluation of single ventricle (see chapter “Single ventricle”), paying particular attention to the ventricular septal defect and the left ventricular outflow tract in patients with tricuspid atresia and transposition of the great arteries (=ventriculoarterial discordance) (Fig. 3.18.3), and to the interatrial septum.

Potential complications

**Modified Blalock-Taussig shunt:** see chapter “Tetralogy of Fallot”.

**Pulmonary artery banding:** see chapter “Ventricular septal defect”.

**Bidirectional Glenn or hemi-Fontan:** see chapter “Single ventricle”.

**Modified Fontan procedure or total cavo-pulmonary connection:** see chapter “Single ventricle”.

![Fig. 3.18.4. Status post bidirectional Glenn anastomosis. CT scan, 3-dimensional angiographic reconstruction, with visualization of the end-to-side superior vena cava to the right pulmonary artery anastomosis and the phase of the pulmonary venous return to the left heart (Ao aorta, IV innominate vein, LV left ventricle, RJV right jugular vein, RLPV right lower pulmonary vein, RPA right pulmonary artery, RUPV right upper pulmonary vein, SVC superior vena cava) (photograph courtesy of Dr. Mohamed Tawil and Cinzia Crawley).](image)

Subaortic resection: complete atroventricular block occurs very rarely, while the risk for either residual or recurrent subaortic obstruction is higher.

Post-operative follow-up

Patients with tricuspid atresia are treated as the patients with a single ventricle (see chapter “Single ventricle”).

Postoperative CT and MRI investigations can provide information on the bidirectional Glenn and on the size and morphology of the right and left pulmonary artery, particularly with regard to the presence and extension of any narrowing (Figs. 3.18.4 and 3.18.5).

magnetic resonance versus routine cardiac catheterization before bidirectional Glenn anastomosis in infants with functional single ventricle. Circulation 116:2718–2725

Definition

Single ventricle (or univentricular heart) is considered a congenital cardiac malformation in which both atria connect to only one ventricular chamber by either two separate atrioventricular valves (double inlet) or a common atrioventricular valve (common inlet). The ventricle to which both atrioventricular valves or a common atrioventricular valve connects is generally well formed, whereas the ventricle not receiving the largest amount of the venous return to the heart is often a rudimentary chamber.

By definition, the term double inlet single ventricle is used only if more than 50% of the overriding valve lies over the main ventricular chamber. When both atrioventricular valves are present, they often cannot be designated as either mitral or tricuspid and are commonly straddling or stenotic. When there is a common atrioventricular valve, it presents frequently with regurgitation.

Most of the hearts described as “single ventricle” or “univentricular heart” in reality possess two ventricular chambers, with one main (dominant) chamber and a second (incomplete) rudimentary chamber which lacks of one or more of its components (generally the inlet, but occasionally also the outlet).

There are three basic patterns of ventricular morphology:

- main ventricular chamber of left ventricular morphology, with rudimentary right ventricle (= single ventricle of left ventricular type),
- main ventricular chamber of right ventricular morphology, with or without rudimentary left ventricle (= single ventricle of right ventricular type),
- single ventricular chamber of indeterminate morphology.

The combination of the type of inlet (double inlet or common inlet) with the type of ventricular morphology (left, right or indeterminate) provide a variety of univentricular atrioventricular connections. This variety is further complicated when other morphological variables are taken in consideration, like the cardiac position (levocardia, mesocardia or dextrocardia), the atrial situs (solitus, inversus, right or left isomerism), the ventriculoarterial connections, the spatial relationship between the main chamber and rudimentary chamber, and the associated cardiac anomalies. The most frequent arrangement is the main chamber of left ventricular morphology with a rudimentary chamber of right ventricular morphology (= single ventricle of left ventricular type). The rudimentary chamber is separated from the main chamber by a septum, which does not extend to the crux of the heart, and is connected to the main chamber via a ventricular septal defect, variously described with interchangeable terms, such as outlet foramen, interventricular foramen, or bulboventricular foramen. Since these hearts do not have a membranous septum, the ventricular septal defect is generally of completely muscular type, with the potential reduction in size typical of the muscular ventricular septal defect in biventricular hearts.
In order to evaluate if the size of the ventricular septal defect is restrictive or unrestrictive, generally its dimensions are related to the size of the corresponding aortic root. The second chamber is always anterior, and is located either to the left or the right. The size of the outlet chamber is related to the degree of development and straddling of the tricuspid valve, in addition to the size of the ventricular septal defect. The ventriculocardiac connections are most commonly discordant and more rarely concordant. Unusual forms of ventriculocardiac connections in double inlet ventricle include double outlet or single outlet (= pulmonary atresia).

Outflow obstruction to the pulmonary artery is common and is the most important determinant of the clinical course. The obstruction may be subvalvular and/or valvular (hypoplastic annulus and/or thickened leaflets), or may be complete (= pulmonary atresia). In the presence of ventriculocardiac concordance the obstruction, mostly dynamic, due to infundibular narrowing, is generally localized at the subvalvular level. In hearts with ventriculocardiac concordance, the obstruction to the pulmonary blood flow is generally due to the presence of a restrictive ventricular septal defect.

Obstruction to the systemic outflow can occur at the subvalvular level and/or the level of the aortic arch and/or isthmus, or at multiple levels. Usually it occurs at the level of the ventricular septal defect in hearts with discordant ventriculocardiac connections; in fact, in these patients, the presence of aortic coarctation and/or aortic arch hypoplasia is a strong marker for the presence of a restrictive ventricular septal defect.

The conduction tissues, with respect to the ventricular septal defect, have a directly comparable arrangement to that seen in tricuspid atresia. This arrangement is seen irrespective of whether the rudimentary right ventricle is right or left sided. The position of the rudimentary ventricle affects only the relationship of the atrioventricular bundle to the outflow tract from the dominant left ventricle. From the surgical point of view, the atrioventricular node can be anywhere around the perimeter of the right-sided (= draining the right-sided atrium) atrioventricular valve.

Associated anomalies

Associated cardiac anomalies occur in about one-third of cases with double inlet ventricle. Anomalous pulmonary and/or systemic venous connections are relatively frequent, particularly in patients with atrial isomerism (see chapter “Isomerism”); the most frequent are persistent left superior vena cava, interruption of the inferior vena cava, partial or total anomalous pulmonary venous connection.

Malformations of the atroventricular valves are also quite common, including straddling, leaflet dysplasia, leaflet cleft and tags, and annular hypoplasia. Aortic arch anomalies such as coarctation, interrupted aortic arch and hypoplastic aortic arch are strongly associated with a restrictive ventricular septal defect in cases in which the aorta arises from the rudimentary chamber (= ventriculocardiac discordance).

Surgical options

Pulmonary artery banding: In these patients, the achievement of an adequate pulmonary artery banding is particularly difficult, considering several interrelated variables that continue to evolve, particularly the need to obtain and maintain a low pulmonary artery pressure, an adequate balance between systemic and pulmonary circulation, at the same time avoiding excessive ventricular pressure overload. A solution to these requirements is pulmonary artery banding with a telemetrically adjustable device (FloWatch-PAB®).

Shunt: A modified Blalock-Taussig shunt (see chapter “Tetralogy of Fallot”) is always the choice for a systemic-to-pulmonary artery shunt.
**Bidirectional Glenn:** The bidirectional Glenn procedure consists of end-to-side anastomosis of the divided superior vena cava to the upper aspect of the right pulmonary artery.

In patients with persistent left superior vena cava, a bilateral bidirectional Glenn procedure (=end-to-side anastomosis of the right superior vena cava to the right pulmonary artery and of the persistent left superior vena cava to the left pulmonary artery, respectively) is performed with the same surgical technique for both anastomoses.

**Hemi-Fontan:** The medial aspect of the superior vena cava and the superior portion of the right atrium are incised as well as the confluence of the right and left pulmonary arteries. In the absence of pulmonary atresia, the proximal stump of the pulmonary artery is divided and oversewn. The superior vena cava is side-to-side anastomosed to the right pulmonary artery, and the same is done in the presence of a persistent left superior vena cava, which is side-to-side anastomosed to the ipsilateral pulmonary artery. A patch of biological (homograft, heterologous pericardium) or prosthetic (PTFE) material is used to augment the pulmonary arteries anteriorly to create a roof over the anastomosis of the vena cava and the pulmonary artery and a dam occluding the inflow of the superior vena cava into the right atrium, leaving a potential connection for the entire systemic venous return larger than the size of the inferior vena cava. An unrestricive interatrial communication is also created, whenever necessary.

**Modified Fontan:** The completion of the Fontan circulation, rerouting the systemic venous return from the inferior vena cava to the pulmonary arteries, can be accomplished with several different surgical techniques, but nowadays the most used remain the following:

Intracardiac lateral tunnel consisting of baffling the inferior vena cava, the superior vena cava and the upper portion of the right atrium with the inferior aspect of the right pulmonary artery with a patch (pericardium, PTFE). The divided stump of the superior vena cava requires augmentation (by a roof of autologous or heterologous pericardium or PTFE) to accommodate the higher systemic venous return coming from the inferior vena cava. The coronary sinus is left in the lower pressure pulmonary venous atrium. An unrestricted interatrial communication is also created, whenever necessary.

Extracardiac connection consisting of an extracardiac connection of the divided inferior vena cava (the cardiac stump is oversewn) to the inferior aspect of the right pulmonary artery by interposition of a non-valved conduit (PTFE, pericardium, in situ pedicled pericardial tunnel), or in exceptional circumstances by direct anastomosis of the transected inferior vena cava to the divided main pulmonary artery.

**Fenestration (=incomplete atrial partitioning):** Different types of fenestration exist to allow for an incomplete separation between the caval and pulmonary venous pathways in order to decompress the systemic venous return. In the lateral tunnel technique, an interatrial communication (generally 4–5 mm diameter) is created in the central part of the prosthetic (PTFE) patch (=fixed fenestration), or is left on the lateral aspect of the suture of the patch. In the extracardiac connection, the extracardiac conduit and the morphologically right atrium (now functioning as the pulmonary venous atrium=collecting chamber for the pulmonary veins and the coronary sinus) are off-bypass connected (=fenestration) either by a tubular prosthesis (PTFE, 6–8 mm diameter) or by side-to-side direct anastomosis. All these types of fenestration will either spontaneously close in the late postoperative period, or they can be electively closed by a percutaneous intervention.

**Ventricular septation:** This procedure can be performed as a single stage with a large patch dividing the two atrioventricular valves and the ventricular cavity, taking
great care to avoid obstruction to the systemic and pulmonary outflow tracts.

*Staged ventricular septation* consists of placing an apical patch and a second patch at the superior portion between the atrioventricular valves, using widely spaced interrupted sutures, with the addition of pulmonary artery banding. Ventricular septation (with debanding) is completed 6–18 months later with a third patch.

### Pre-operative information

Classically single ventricle is fully diagnosed and evaluated by echocardiography and cardiac catheterization. The following pre-operative information is required at all stages:

- situs and position of the heart,
- systemic and pulmonary venous connections,
- interatrial communication,
- ventricular septal defect,
- atrioventricular valves (morphology and function),
- ventricular anatomy, function, mass and myocardial viability,
- ventricular outflow tract (level of potential obstruction),
- ventriculoarterial connections,
- aortic arch (morphology and potential obstruction),
- sources of pulmonary blood flow,
- pulmonary arteries morphology, pressures and resistance.

Due to the high potential diagnostic value already discussed in the "Introduction", cardiac CT (Fig. 3.19.1) and MRI (Fig. 3.19.2) are gaining widespread interest in such patients as they could provide, in conjunction with echocardiography, all the required information with exception of the pulmonary pressure and resistance. There is general agreement that, in selected patients without suspected high pulmonary artery pressure, cardiac MRI could be used to avoid cardiac catheterization in many instances as patients progress through staged Fontan circulation. Furthermore, MRI’s unique ability to accurately detect volume and mass of such bizarre shaped ventricles makes it capable of providing us anatomical and functional information not available by any other diagnostic tool.

The following MRI protocol is used in the evaluation of functionally single ventricle:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the "Introduction"); the two previous types of imaging, mainly the latter, can greatly help in defining the bronchial anatomy, hence allowing potential sidedness anomalies to be confirmed (Fig. 3.19.2a–c),
- ECG-gated cine steady-state free precession sequences in straight axial, sagittal, coronal and additional oblique planes in order to show the whole heart on three orthogonal planes; even if it is of long duration, it better visualizes the intracardiac anatomy, its connections and spatial disposition inside the thorax (Fig. 3.19.2f–h),
- ECG-gated cine steady-state free precession sequences on the ventricular long and short axis plane, for the quantitative assessment of ventricular dimensions, function, mass and stroke volume,
- ECG-gated cine steady-state free precession and fast spin echo sequences to vi-
visualize the ventricular outflow tract, the ventricular septal defect and their relationship (Fig. 3.19.2 k and l),

- ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending aorta, and pulmonary arteries, to assess the flow pattern in the great arteries,

- gadolinium-enhanced MR angiography for the evaluation of the pulmonary arteries and veins, systemic venous connections, aortic arch and any aortopulmonary collaterals (Fig. 3.19.2 m and n).

### Potential complications

- **Pulmonary artery banding:** potential for pulmonary artery distortion, development of pulmonary valvular regurgitation or damage to the pulmonary valve, progressive ventricular hypertrophy, decreased ventricular compliance, and development of subvalvular aortic stenosis. Subaortic stenosis often follows palliative pulmonary artery banding, in which the resultant hypertrophy of muscle around the ventricular septal defect may play a contributing role (Fig. 3.19.3).
Bidirectional Glenn: prolonged pleural and/or pericardial effusions, chylothorax, phrenic nerve lesion. A persistently high pulmonary vascular resistance results in insufficient pulmonary blood flow and severe cyanosis, manifested by high superior vena cava pressure (over 18–20 mmHg). An elevated superior vena cava pressure may significantly decrease cerebral perfusion by decreasing the pressure gradient across the cerebral bed. This may be clinically manifested as fullness and pulsatility of the fontanelle, persistently irritability, systemic hypertension and relative bradycardia. Following the bidirectional Glenn procedure, potential late development of pulmonary arteriovenous malformations or venovenous collaterals may cause severe cyanosis. The latter results in right-to-left shunt, and, if severe, precludes successful conversion to Fontan operation.

Hemi-Fontan operation: distortion or degeneration of the biological or prosthetic materials used for the central pulmonary arteries augmentation and early or late supraventricular arrhythmias are potential complications in addition to those listed for the bidirectional Glenn procedure.

Modified Fontan procedure: in the presence of a failing Fontan procedure, the potential obstruction at any level of the cavo-pulmonary connections, as well as the persistence of intracardiac shunts (other than the surgically created fenestration), must always be ruled out. The most frequent early complications are prolonged pleural effusion and chylothorax; chronic venous stasis, recurrent pericardial effusion, ascites, fluid retention, renal failure, hepatic failure and gastrointestinal dysfunction are more frequent
in higher risk patients. While sinus node dysfunction, atrial fibrillation or flutter is more frequent, ventricular arrhythmias are less frequent, and complete atrioventricular block is very rare. Thromboembolism can occur in about 10% of patients, particularly in the presence of a low-output state with low velocity flow through the venous pathway.

Protein-losing enteropathy (reduced serum albumin concentration accompanied by diarrhea, poor appetite, failure to grow), pulmonary arteriovenous malformations and venovenous collateral formation (between brachiocephalic angles and pericardial veins, azygos and hemiazygos system, Thebesian veins and epidia phragmatic veins) with systemic arterial desaturation are the most frequent late complications. Exercise intolerance (or reduced exercise capacity) is observed in a certain percentage of patients as well as progression of atrioventricular valve regurgitation. Persistent and/or progressive hypoxemia can occur after the Fontan procedure, further increased with exercise, even in the absence of evident intracardiac right-to-left shunt. The reason is probably the presence of a mild intrapulmonary shunt and the drainage of the coronary sinus into the pulmonary venous atrium. Plastic bronchitis is very rare but mostly accompanied by dramatic consequences.

Either a fenestration (when absent or inadequate) or the early or late take-down of the total cavopulmonary connection is sometimes necessary, with or without associated
treatment for the supraventricular arrhythmias. Heart transplant is sometimes the only available solution, when pulmonary vascular resistance is still within the normal range.

**Ventricular septation:** the incidence of complications with ventricular septation, except for a very well selected cases, remains elevated. Potential complications are obstruction to the systemic and/or pulmonary inflow and/or outflow tracts, distortion of the atrioventricular valve(s) with resulting regurgitation, lesion of the coronary arteries, residual interventricular shunt, complete atrioventricular block.

**Fig. 3.19.3.** Double inlet ventricle, status-post pulmonary artery banding. MRI para-coronal cine steady-state free precession double inlet ventricle and transposition of the great arteries after pulmonary banding with subaortic turbulent flow (head arrow) (Asc Ao ascending aorta, LV left ventricle, PAB pulmonary banding)

**Fig. 3.19.4.** Single ventricle with restrictive ventricular septal defect, status post Fontan procedure. MRI fast spin echo para-coronal scan showing a restrictive ventricular septal defect in a patient after Fontan procedure. Note the malalignment of the trabecular septum with a restrictive inlet type of ventricular septal defect extended to the outlet septum, leading to subaortic stenosis.
Post-operative follow-up

The following targets have to guide the post-operative evaluation:

- anatomy, size and flow pattern of the bi-directional cavopulmonary anastomosis or of the total cavopulmonary anastomosis,
- ventricular volume, mass and function,
- atrioventricular valve (or valves) evaluation,
- anatomy of the ventricular septal defect, particularly in case of aorta arising from the accessory chamber (Fig. 3.19.4),
- detection of thrombi, particularly at atrial level, in case of “old fashion” Fontan procedure, consisting in direct atrio-pulmonary anastomosis leading to huge right atrial enlargement.

Echo-Doppler, as the first line diagnostic tool, is very useful. However, previous surgical scars, growing body mass, baffles and conduits deeply located inside the thorax and bizarre ventricular geometry make this type of echocardiographic investigation technically challenging and sometimes is not exhaustive enough to accurately cover all the previously mentioned targets, like ventricular function and flow pattern assessment.

On the other hand, cardiac MRI is gaining an increasingly important role in the evaluation of such patients by overcoming some of the echocardiography drawbacks (Fig. 3.19.5). By means of steady-state free precession and phase velocity contrast acquisition, today MRI is the best way to assess ventri-
cicular volume, mass and function, and flow pattern, respectively, in patients with single ventricle after bidirectional Glenn or Fontan procedures. Moreover, by means of the “delay enhancement” technique, myocardial fibrosis can also be detected. Myocardial tagging is performed in some MRI laboratories to further evaluate ventricular function and mechanics. In selected patients with normal pulmonary artery pressure and resistance, a comprehensive cardiac MRI, in addition to clinical and echocardiography evaluation, can avoid the need of cardiac catheterization before Fontan completion.

The post-operative protocols used are the same as in the pre-operative evaluation, with the addition of the evaluation of the bidirectional Glenn or Fontan pathways:

- ECG-gated cine steady-state free precession and fast spin echo sequence targeted at the cavopulmonary anastomosis and the fenestration,
- ECG-gated phase velocity contrast MRI sequences perpendicular to the ascending aorta, pulmonary arteries, superior and inferior vena cava, Fontan conduit, and pulmonary veins to assess the Fontan pathway flow (Fig. 3.19.6),
- ECG-gated axial double inversion fast spin echo at the atrial level to check for clots or masses, mainly in case of direct atrio-pulmonary anastomosis (Fig. 3.19.7),
- gadolinium-enhanced 3-dimensional MR angiography for the evaluation of the Fontan pathway including systemic venous return, conduit, pulmonary arteries and pulmonary veins, and the aortic arch (Fig. 3.19.8). Because of the particular Glenn or Fontan “physiology”, the technique of the contrast medium injection...
(site of injection, bolus velocity and amount contrast) is challenging; sometimes it is useful to inject the contrast medium through an inferior limb vein instead of using a superior limb vein as normally done to better visualize the inferior vena cava-pulmonary artery conduit,

post-gadolinium delayed myocardial enhancement to evaluate the presence of scar tissue in 2-chamber and ventricular short-axis plane (Fig. 3.19.9).

Adequate information from the CT scan can be obtained using the early phase acquisition protocol with injection of contrast material into the right cubital vein and using the step volume scan mode of electron-beam CT. With 3-dimensional image reconstruc-
tion, the blood flow through the bidirectional Glenn anastomosis and the complex morphology and relationship between adjacent structures can be directly demonstrated (Fig. 3.19.10). Information is provided on the size and morphology of the right and left pulmonary arteries, particularly with regard to the presence and extent of any narrowing.

Fogel MA (2005) Is routine cardiac catheterization necessary in the management of patients with single ventricles across staged Fontan reconstruction? No! Pediatr Cardiol 26:154–158

**Definition**

Hearts with pulmonary atresia with ventricular septal defect have a biventricular arrangement, concordant atrioventricular connections, unrestrictive ventricular septal defect, single aortic outlet and absent luminal continuity between the right ventricle and the pulmonary arterial circulation.

The ventricular septal defect, usually unrestrictive, is generally of the malalignment type, resulting from extreme anterior deviation of the infundibular septum. The aorta can be entirely connected to the left ventricle or may override the interventricular septum (26–50% of cases). Pulmonary atresia resulting from anterior deviation of the infundibular septum (like in tetralogy of Fallot) with underdevelopment of the right infundibular outflow tract and atretic infundibulum is the most common type (70% of the cases). More rarely, pulmonary atresia can involve the pulmonary valve alone or the pulmonary valve and the proximal portion of the main pulmonary artery, or it may involve a longer segment of the main pulmonary artery. The main pulmonary artery can be present and be of reasonable size but in most of cases is severely hypoplastic; more rarely, it consists of only a fibrous cord without lumen and in 5% of the patients is completely absent.

The morphology of the central pulmonary arteries is highly variable. The central right and left pulmonary arteries may be present and communicate freely (confluent pulmonary arteries) or may not communicate (nonconfluent pulmonary arteries, 20–30% of patients) or may be absent. Stenosis at the origin of the right pulmonary artery is present in 10% of the cases, while there is stenosis of the left pulmonary artery in 20% of cases, probably because of the process of closure of the ductus arteriosus. The size of the prebranching pulmonary arteries is extremely variable, and it can be quantitated with two different indexes: the McGoon ratio (see reference: Pehler JM), consisting of the ratio between the sum of the diameters of the right plus the left pulmonary artery divided by the diameter of the descending thoracic aorta at the level of the diaphragm, and the Nakata index (see reference: Nakata S), consisting of the ratio between the sum of the crosssectional areas of the right plus left pulmonary artery divided by the body surface area of the patient.

The pulmonary circulation is highly variable and it may be supplied by a patent ductus arteriosus, major aortopulmonary collateral arteries (in 60–70% of cases), or plexuses of bronchial and pleural arteries (5%). Only about half (53%) of patients with confluent pulmonary arteries present with pulmonary arteries reaching all 20 pulmonary segments, while less than 20% of patients with nonconfluent and/or hypoplastic pulmonary arteries have complete distribution of pulmonary arteries to all pulmonary segments. The major aortopulmonary collateral arteries may anastomose at any site in the pulmonary vascular tree: extrapulmonary, hilar, lobar and segmental levels. Rare
complex cases have been reported with simultaneous presence of patent ductus arteriosus and major aortopulmonary collateral arteries, and exceptionally with the presence of bilateral (right and left) ductus arteriosus. Major collateral arteries typically arise from the descending thoracic aorta, less commonly from the subclavian arteries, and rarely from the internal mammary (thoracic) arteries, intercostal arteries, carotid arteries or abdominal aorta; extremely rare cases have been reported with collateral arteries arising from coronary arteries. After a complex course in the posterior mediastinum, collaterals provide pulmonary blood flow either terminally or communicating with native proximal or distal pulmonary arterial branches. They may feed one side of the lungs, both sides or cross to the opposite side. Because of processes of intimal proliferation, major collaterals can develop stenosis in up to 60% of the patients. They may evolve quite variably and unpredictably, and may have a protective effect on pulmonary microvasculature. However, they may also complicate the surgical treatment of the disease.

Associated anomalies

Like tetralogy of Fallot with pulmonary stenosis, 25–30% of these patients have a dilated right aortic arch. Other anomalies include dextrocardia, heterotaxia, anomalous pulmonary or systemic venous connections, atrial septal defect or patent foramen ovale (50%), atrioventricular septal defect, tricuspid atresia, double inlet single left ventricle, aortic valve stenosis, complete transposition of the great arteries, double discordance (= congenitally corrected transposition of the great arteries), anomalous coronary arteries or coronary artery-to-pulmonary artery fistulas.

Surgical options

**Unifocalization with central shunt or right ventricular outflow tract reconstruction without closure of the ventricular septal defect.** Through a median sternotomy all the major aortopulmonary collateral arteries are separated from their systemic origin and joined together to construct a pulmonary artery confluence, either with direct anastomoses or with the interposition of an autologous or heterologous pericardial roll; the pulmonary blood flow is obtained either with a central shunt (PTFE tubular prosthesis) or a valveless conduit (PTFE or pericardial) or a biological valved conduit interposed between a right ventriculotomy and the pulmonary artery reconstructed confluence. The ventricular septal defect is left open, or it may be closed with a fenestrated PTFE patch to allow right ventricular decompression, with later closure by interventional cardiology.

**Single-stage unifocalization and complete repair.** The unifocalization of the major aortopulmonary collateral arteries is performed as for the two-stage repair (see above); the ventricular septal defect is closed from a longitudinal right ventriculotomy with a prosthetic patch, leaving the aortic valve in communication with the left ventricle; the right ventricle to pulmonary artery continuity is obtained with a biological valved conduit (rarely a monocusp valve patch or a valveless conduit is used) interposed between the same right ventriculotomy used for closure of the ventricular septal defect and the pulmonary artery reconstructed confluence.

In the presence of favorable anatomy with adequate right ventricular outflow tract and confluent pulmonary arteries, the first step consists of right ventricular outflow tract reconstruction with pericardial patch and closure of the ventricular septal defect.
Alternative surgical approach. The segment of descending thoracic aorta containing the origin of all the collaterals is transected and replaced with a PTFE conduit. The distal end of the above segment is closed by running suture, while the proximal end is end-to-side anastomosed to the native pulmonary artery confluence. At this point, the conventional intracardiac repair is performed, with patch closure of the ventricular septal defect and interposition of a biological valved conduit between the right ventricle and the confluence between the native pulmonary arteries and the transected aortic segment.

Pre-operative information

Pulmonary atresia with ventricular septal defect requires a pre-operative approach similar to tetralogy of Fallot (see chapter), with the only difference being that antegrade pulmonary blood flow, by definition, is lacking. Therefore, the pre-operative identification of any pulmonary blood flow source (patent ductus arteriosus and/or major aortopulmonary collateral arteries) and the morphology of the pulmonary arteries is mandatory for the decision-making process (either unifocalization of the sources of pulmonary blood flow or shunt or even interventional embolization). This is particularly true in neonates with pulmonary atresia, ventricular septal defect and nonconfluent pulmonary arteries. In these cases, CT scan and/or MRI, each one with its own advantages and disadvantages already discussed in the “Introduction”, are very useful (Figs. 3.20.1–3.20.4).

Potential complications

Inadequate and/or dishomogeneous distribution of pulmonary blood flow; congestive heart failure, due to the persistence of uncontrolled major aortopulmonary collateral arteries; residual or recurrent ventricular septal defect; complete atrioventricular block, ventricular or supraventricular arrhythmias; persistent airway hyperresponsiveness with or without bronchomalacia; bronchospasm due to tracheobronchial epithelial necrosis or ischemia due to airway ischemia resulting from interruption of the tracheobronchial blood supply during dissection and mobilization of major aortopulmonary collaterals; pulmonary artery aneurysm; development of pulmonary vascular obstructive disease; development or progressive increase of aortic valve regurgitation; need for biological conduit replacement because of conduit calcification and/or valve degeneration (= pulmonary valve regurgitation) or because patient outgrew the conduit size (= right ventricular outflow tract obstruction).

Post-operative follow-up

Targets of the postoperative evaluation are the same as for patients with tetralogy of Fallot, with the addition of the unifocaliza-
Fig. 3.20.2. Pulmonary atresia with ventricular septal defect. 

a CT contrast angiography, anterior projection, showing a single great artery (aorta) coming from the heart, right aortic arch, and a long patent ductus arteriosus originating from the left innominate artery with a stenotic connection to the left pulmonary artery (arrow) (AAo ascending aorta, IA innominate artery, LV left ventricle, RAA right aortic arch, RV right ventricle). 
b CT contrast angiography, posterior projection in the same neonate, showing the right aortic arch, the patent ductus arteriosus originating from the left innominate artery with a stenotic connection to the left pulmonary artery (white arrow), and several major aorto-pulmonary artery collaterals (red arrows) originating from the left subclavian artery (X1) and from the descending thoracic aorta (X2) (DTAo descending thoracic aorta, LPA left pulmonary artery, LV left ventricle, RAA right aortic arch). 
c CT contrast angiography, in the same neonate, showing the patent ductus arteriosus with a stenotic connection to the left pulmonary artery (white arrow), and several major aorto-pulmonary artery collaterals mostly perfusing the right lung (LPA left pulmonary artery, LPVs left pulmonary veins, LV left ventricle, RPVs right pulmonary veins) (photographs courtesy of Dr. Mohamed Tawil)
Pulmonary atresia with ventricular septal defect

Fig. 3.20.4. Pulmonary atresia with ventricular septal defect, major aortopulmonary collateral arteries and absent main pulmonary artery. MR angiography (maximal intensity projection reconstruction) showing several major aortopulmonary collateral arteries at different aortic levels (a and b) (DAo descending aorta, MAPCA major aortopulmonary collateral artery)
tion of the major aortopulmonary collateral arteries. After palliative procedures, CT and MR angiography are valuable tools to show the surgically created systemic-to-pulmonary artery shunts, the relationship between the surgical shunts and the pulmonary arteries, the presence of pulmonary artery aneurysm (Fig. 3.20.5) and particularly the results of surgical procedures of unifocalization of the major aortopulmonary collateral arteries.

After repair, MRI is particularly useful to evaluate biventricular function, pulmonary vascularization, potential residual lesions like residual ventricular septal defect, pulmonary valve regurgitation, right ventricular outflow tract obstruction, and finally ascending aortic dilatation and aortic valve regurgitation (Figs. 3.20.6 and 3.20.7). Therefore, the MRI protocol of postoperative pulmonary atresia with ventricular septal defect

**Fig. 3.20.5.** Pulmonary atresia with ventricular septal defect, status post right modified Blalock-Taussig shunt and huge left and right pulmonary aneurysm. Maximal intensity projection reconstruction from MR angiography: anterior (a) and posterior (b) view showing a left major aortopulmonary collateral arteries. Fast spin echo in the oblique frontal plane (c) illustrating a patent right modified Blalock-Taussig shunt and left pulmonary aneurysm with thrombi stratification. Axial projection. e MR angiography volume rendering reconstruction: note the unusual anatomy of the pulmonary arteries and the right and left pulmonary aneurysm (Ao aorta, DAo descending aorta, LPA left pulmonary artery, MAPCAs major aortopulmonary collaterals, MPA main pulmonary artery, mBT modified Blalock-Taussig shunt, RPA right pulmonary artery)
is similar to the postoperative Fallot (see chapter “Tetralogy of Fallot”). In case of multiple previous interventional procedures of embolization, MRI can be nondiagnostic due to major artifacts coming from coils positioned during the embolization procedures.

Chapter 3.21 Truncus arteriosus

**Definition**

There is only one great artery (truncus arteriosus) originating from the base of the heart providing both pulmonary and systemic circulation. The truncal valve is obviously larger than a normal semilunar valve, with a variable number of leaflets from only one up to five and even six leaflets (extremely rare); most frequently the truncal valve has three (42–61% of cases) or four leaflets (24–31% of cases); a truncal valve with two leaflets is rare (5% of cases). The valve is generally located above the ventricular septal defect, almost always present, and the leaflets can be dysplastic and/or thickened with resulting stenosis, regurgitation (in at least 20% of cases), or both. The ventricular septal defect results from the absence of the infundibular septum, and is generally high, anterior and unrestrictive. Absence of the ventricular septal defect is anecdotal.

The pulmonary arteries can originate as a single main pulmonary artery from the lateral aspect of the truncus arteriosus (type I of the Collett and Edwards classification, the most frequent), or with two very close but separate origins from the posterolateral aspect of the truncus arteriosus (type II, the second frequent), or with the two pulmonary arteries independently originating from a lateral aspect of the truncus arteriosus (type III). The truncus arteriosus with neither pulmonary arterial branch arising from the truncus arteriosus (so called type IV) is considered as a variant of pulmonary atresia and ventricular septal defect with absent pulmonary arteries (see chapter “Pulmonary atresia with ventricular septal defect”). Stenosis at the origin of one or both branches of the pulmonary arteries is reported in 2 to 10% of patients. The origin of the coronary arteries presents with variable pattern, independent of the number of truncal valve leaflets.

**Associated anomalies**

Ventricular septal defect is almost always present, right aortic arch is frequent (18–36%), as well as truncal valve regurgitation (23%) or stenosis and coronary arteries abnormalities (18%), including single coronary artery and intramural course; aortic arch interruption, usually of type B (11–14%), and aortic coarctation are accompanied by patent ductus arteriosus; more rare (5%) is the association with nonconfluent pulmonary arteries, the so-called “absent” pulmonary artery, where one of the pulmonary arteries originates either from a patent ductus arteriosus or from a major aortopulmonary collateral; persistent left superior vena cava, total anomalous pulmonary venous connection, tricuspid atresia, complete atrioventricular septal defect, single ventricle, double aortic arch, anomalous origin of circumflex coronary artery from right pulmonary artery, situs inversus, dextrocardia have been exceptionally reported.

**Surgical options**

Palliative approaches with bilateral pulmonary artery banding or plication of the origin of the pulmonary artery component have been practically abandoned in favor of surgical repair.
The surgical technique consists of three major components:
- separation of the pulmonary artery component from the truncus; at this point the truncus becomes the new aorta; the remaining opening in the lateral aspect of the truncus can be closed either directly or with a patch (pericardium or PTFE), based on the size and particularly on the presence of a coronary artery originating in the proximity of the opening itself; either technique to close the residual opening (direct or patch) needs to avoid traction or tension of the coronary arteries, and in this regard patch closure is the preferable technique,
- closure of the ventricular septal defect with a patch from a longitudinal right ventriculotomy, leaving the remaining systemic artery (becoming the aorta) in connection only with the left ventricle, and avoiding damage to the truncal valve (becoming the aortic valve),
- connection of the pulmonary artery component with the right ventricle by interposition of a biological valved conduit; valveless conduits are more rarely used; alternatively it is possible to perform direct anastomosis of the posterior wall of the pulmonary component to the posterior edge of the right ventriculotomy, completing the connection with a pericardial or PTFE roof, with or without a monocusp pulmonary valve (technique rarely utilized).

Associated lesions, particularly the presence of aortic coarctation or aortic arch interruption, need to be treated during the same procedure.

In the presence of moderate to severe truncal valve regurgitation, particularly with a quadrileaflet valve, a plasty by reduction to three leaflets with leaflet excision and annular remodeling can substantially reduce the degree of valvular regurgitation. More difficult to perform is the surgical opening of a stenotic truncal valve with adequate results. Truncal valve replacement (with a homograft or mechanical valve) needs to be taken into consideration in case reconstructive valvular surgery fails.

**Pre-operative information**

Truncus arteriosus can be sufficiently evaluated, mainly in neonates, by transthoracic echocardiography. Nevertheless in older patients or if more anatomical details about the pulmonary arteries and venous connections as well as aortic arch are needed, CT scan and MRI can give more valuable insight. The role of CT scan and cardiac MRI is to delineate the precise morphology of the arterial trunk, with identification of the origin of the pulmonary arteries accordingly with the type of truncus arteriosus (type I, II or III), the distance between the origin of the pulmonary component and the origin of the left main coronary artery, and potential anomalies of the coronary arteries (Fig. 3.21.1).

CT scan and MRI are particularly useful in case of associated anomalies, in particular of disconnected pulmonary arteries or a so-called absent pulmonary artery, where the left or the right pulmonary artery originates.

---

**Fig. 3.21.1.** Truncus arteriosus. CT scan, axial projection, showing a quadricuspid truncal valve with single origin of the coronary arteries with association with the posterior commissura (arrow) (LCA left coronary artery, RCA right coronary artery, TV truncal valve) (photograph courtesy of Dr. Mohamed Tawil)
from a ductus arteriosus or from a major aortopulmonary collateral artery. In these cases, even angiography can fail to reveal the presence and location of the absent pulmonary artery, well visualized by CT scan or MRI.

CT scan and MRI play the same important role in the presence of aortic coarctation or aortic arch interruption, where the precise identification of the aortic arch morphology can allow better surgical planning (Fig. 3.21.2).

Finally, in the presence of airway compression, particularly frequent with right aortic arch, where tracheal and left bronchial compression are often associated, the simultaneous visualization of the great arteries and the airways provides vital information for the decision-making process when planning surgical repair of the truncus arteriosus associated with surgical relief of airway compression.

Due to radiation exposure considerations already highlighted in the introduction, MRI is considered the second choice diagnostic tool after echocardiography for the evaluation of truncus arteriosus with complex anatomy.

The pre-operative MRI protocol includes:
- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the "Introduction"),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume (as illustrated in appendix in the introduction chapter),

Fig. 3.21.2. Truncus arteriosus. MR Angiography volume rendering reconstruction, posterior (a) and lateral (b) view, showing the truncus arteriosus type III with separate origin from its lateral and posterior aspect of relatively small pulmonary arteries and severe kinking of the transverse aortic arch. (c) MRI fast spin echo imaging showing the tracheal compression due to the transverse aortic arch (photographs courtesy of Dr. Philipp Beerbaum and Dr. Robert A. Johnson)
ECG-gated steady-state free precession left ventricular outflow tract,
ECG-gated steady-state free precession short axis of the truncal valve,
ECG-gated fast speed echo to visualize potential airway obstruction,
ECG-gated phase velocity contrast MRI sequences perpendicular to the main trunk for the quantification of truncal valve regurgitation,
gadolinium-enhanced 3-dimensional MRI for the evaluation of the aortic arch, pulmonary arteries and ductus arteriosus if patent.

Potential complications

Residual ventricular septal defect, complete atroventricular block, arrhythmias, residual or progressive truncal valve stenosis or regurgitation, residual right ventricular outflow tract obstruction, pulmonary hypertension, airways compression (particularly in the presence of right aortic arch and aortic coarctation or aortic arch interruption). Late complications are progressive truncal valve dysfunction and obstruction of the right ventricle to pulmonary artery conduit.

Post-operative follow-up

The role of CT scan and MRI in patients after repair of truncus arteriosus increases with their age. The anatomic and functional issues in these patients are similar to those encountered in patients after repair of tetralogy of Fallot with pulmonary atresia and pulmonary atresia with ventricular septal defect (Fig. 3.21.3). In addition, neoaortic valve dysfunction, aortic arch obstruction and potential airway compression are additional issues that may require further investigation.

Fig. 3.21.3. Truncus arteriosus, status post-repair. a CT scan, sagittal projection, showing the valved conduit with calcifications (arrows) on the free wall. b CT scan in the same patient, axial projection, showing the truncal valve (Ao aorta, LA left atrium, LPA left pulmonary artery, LV left ventricle, MP main pulmonary artery, RPA right pulmonary artery, RV right ventricle, TV truncal valve, VC valved conduit) (photographs courtesy of Dr. Mohamed Tawil)
Fig. 3.21.4. Truncus arteriosus Type I, status post repair with a homograft. Cardiac MRI late after repair of truncus arteriosus, with severe aortic regurgitation. Steady-state free precession cine imaging of the left ventricular outflow tract (a) showing the aortic regurgitation jet (40% regurgitant fraction calculated by phase velocity contrast-MRI). Short-axis cine imaging steady-state free precession of the aortic valve in diastole (b) and systole (c) and fast spin echo in diastole (d): note the defect of coaptation (blue arrow) secondary to hypoplastic left coronary leaflet. The left ventricle, shown in the steady-state free precession 4-chamber view (e), is dilated (Z-score = +4 in diastole). The acquisition late after I.V. injection of gadolinium (delayed enhancement) (f) demonstrate a 3 cm long subendocardial fibrosis (arrow) in association with the left side of the lower portion of the interventricular septum. Cine imaging (steady-state free precession) of the right ventricular outflow tract (g) and 3-dimesional MR angiography (volume rendering reconstruction) (h) showing mild stenosis of the pulmonary homograft and pulmonary arteries (AO aorta, LA left atrium, LC left coronary artery, LPA left pulmonary artery, LV left ventricle, NC noncoronary, PA pulmonary artery, RA right atrium, RC right coronary, RPA right pulmonary artery, RV right ventricle, RV-PA Homograft).
Fig. 3.21.5. Truncus arteriosus Type IV, status post repair with a pericardial patch for right ventricular outflow tract reconstruction and end-to-end anastomosis for the interrupted aortic arch. Cardiac MRI maximal intensity projection (a) and volume rendering reconstruction (b) showing the stamped ascending aorta and aortic isthmus stenosis. Volume rendering reconstruction (c) showing the pulmonary bifurcation shifted anterior to the ascending aorta during the Lecompte maneuver (Ao Arch aortic arch, Ao root aortic root, Asc Ao ascending aorta, Disc Ao descending aorta, LA left atrium, LPA left pulmonary artery, Pulm pulmonary, RPA right pulmonary artery, RVOT right ventricular outflow tract).
The goals of the post-operative MRI examination include: 1) quantitative assessment of left and right ventricular volumes, function, and mass; 2) measurements of pulmonary and neoaortic valve regurgitation; 3) imaging of the right ventricular outflow tract, the valved conduit, and the branch pulmonary arteries; 4) assessment of residual shunts; and 5) imaging of the aortic arch and isthmus (Figs. 3.21.4 and 3.21.5).

Modifications of the MRI protocol described for tetralogy of Fallot are individualized for the patient's anatomic and hemodynamic characteristics:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the "Introduction"),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume (as illustrated in the appendix in the "Introduction"),
- ECG-gated cine steady-state free precession para-sagittal sequence to visualize the left ventricular outflow tract and the aortic arch,
- ECG-gated cine steady-state free precession sequence short axis of aortic (previous truncal) valve,
- ECG-gated cine steady-state free precession sequence, generally on the sagittal plane, to visualize the right ventricular outflow tract,
- ECG-gated fast spin echo of the aortic arch when required,
- gadolinium-enhanced 3-dimensional MRI for the evaluation of great arteries and aortic arch,
- ECG-gated phase velocity contrast MRI sequences perpendicular to main pulmonary artery, ascending aorta and pulmonary arteries, to assess aortic and pulmonary valve regurgitation, pulmonary blood flow, and post-gadolinium delayed myocardial enhancement may be used to evaluate the presence of fibrotic tissue.

McGoon DC, Rastelli GC, Ongley PA (1968) An operation for the correction of truncus arteriosus. JAMA 205:69–73
Aortopulmonary window is a communication, usually nonrestrictive, between the ascending aorta and the main pulmonary artery, in the presence of two semilunar valves. In most patients, there is little or no length to the communication, as the term window implies, while a ductus-like type of communication is rare. The aortopulmonary window is generally located in the left lateral wall of the ascending aorta, usually close to the orifice of the left coronary artery (Fig. 3.22.3); therefore it is not infrequent to find an anomalous origin of the coronary artery from the pulmonary artery, close to the edge of the defect.

Associated anomalies
Associated defects are present in 30–50% of patients, the most frequent being aortic arch interruption type A, tetralogy of Fallot with or without pulmonary atresia, ventricular septal defect, anomalous origin of a coronary artery and anomalous origin of a pulmonary artery; occasional an association with atrial septal defect, cor triatriatum, complete atrioventricular septal defect, transposition of the great arteries, subaortic obstruction (extremely rare), bicuspid aortic valve, aortic atresia, critical pulmonary valve stenosis, aortic arch hypoplasia, aortic coarctation, double aortic arch, and patent ductus arteriosus.

Surgical options

Ligature: nowadays, this surgical approach is limited to exceptional cases with aortopulmonary window with “ductus-like” morphology, with relatively small diameter and long shape.

Closure on cardiopulmonary bypass: the surgical approach can be transaortic, transpulmonary, transdefect or combined transaortic and transpulmonary, according to the morphology of the defect and the personal experience of the surgeon. In any case, after initial opening of the aortic side or of the anterior wall of the defect, the origin of the coronary arteries and the origin of the right pulmonary artery must be very carefully identified. Thus, the transpulmonary approach is not ideal, because it does not allow adequate visualization of the origin of the coronary arteries.

Patch closure with a prosthetic or pericardial patch is always preferred to direct closure to avoid distortion of the surrounding structures, particularly the origin of the coronary arteries. In the presence of anomalous origin of a coronary artery, tunnel or coronary artery reimplantation is required in order to leave the origin of the anomalous coronary artery connected with the aortic side of the circulation.
Pre-operative information

The clinical data and the echocardiographic investigation generally provide enough information for the diagnosis of aortopulmonary window. Other noninvasive investigations, such as CT scan (Figs. 3.22.1 and 3.22.2) and/or MRI (Figs. 3.22.3 and 3.22.4), allow clear visualization of the location of the aortopulmonary window and can precisely show its relationship with the origin of the coronary arteries. CT scan and MRI become extremely important in order to better plan the surgical approach in the presence of asso-
ciated anomalies, e.g., aortic arch interruption, aortic arch hypoplasia with or without aortic coarctation, anomalous origin of a pulmonary artery, and anomalous origin of a coronary artery from the pulmonary artery.

The cardiac MRI protocol used in the presence of aortopulmonary window is the following:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix in the “Introduction”),

**Fig. 3.22.5.** Aortopulmonary window, status post repair. Post-operative CT scan in the same patient of Fig. 3.22.1, axial projection, showing absence of any residual shunt or stenosis in the ascending aorta and main pulmonary artery (Ao aorta, PA pulmonary artery) (modified with permission from Zhang X, Wu ZK, Yao JP, Sun PW (2004) Aortopulmonary window: a case diagnosed and surgery confirmed by ultrafast computed tomography. Chin Med J 117:1750–1752)

**Fig. 3.22.4.** Aortopulmonary window. a MR angiography axial maximal intensity projection reconstruction in a neonate showing the aortopulmonary window (arrow). b MR angiography maximal intensity projection reconstruction in the same neonate showing the aortopulmonary window (arrow). c MR angiography maximal intensity projection reconstruction in the same neonate, showing the aortopulmonary window (arrow) (AAo ascending aorta, AoA aortic arch, MPA main pulmonary artery)
ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume, as illustrated in the appendix of the “Introduction”,

ECG-gated cine steady-state free precession and static fast spin echo sequences on additional planes to better delineate the aortopulmonary window,

ECG-gated static 3-dimensional steady-state free precession for the evaluation of origin and proximal course of the coronary arteries,

ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery branches and ascending aorta to assess the amount of shunt,

gadolinium-enhanced 3-dimensional MRI for the evaluation of potential associated anomalies of the aortic arch.

Potential complications

Residual or recurrent left-to-right shunt, residual or progressive obstruction of the ascending aorta or the main pulmonary artery, obstruction of a coronary artery origin.

Post-operative follow-up

In the follow-up of patients after surgical repair of aortopulmonary window, CT scan and/or MRI are indicated to rule out residual aortopulmonary distortion (Fig. 3.22.5). Meanwhile MRI by means of cine MR and phase velocity contrast acquisitions can respectively visualize and measure residual shunts at the aortopulmonary window, or to rule out residual defects after the repair of associated malformations.

Definition

The anomalous origin of the pulmonary artery (also called “hemitruncus”) is a rare congenital malformation in which only one pulmonary artery branch, usually the right (opposite to the laterality of the aortic arch), originates from the posterior aspect of the ascending aorta just above the aortic sinotubular junction, without any defect between the ascending aorta and the main pulmonary artery, whereas the main pulmonary artery and the other pulmonary artery branch arise in their normal position and, therefore, are connected with the morphological right ventricle. The other main difference with persistent truncus arteriosus is the presence of two well-separated semilunar valves, aortic and pulmonary valves, and the usual absence of ventricular septal defect. Therefore, hemitruncus defines only the anomalous origin of one pulmonary artery. The anomalous pulmonary artery, most frequently the right, has unrestricted origin, and normal structure, course and distribution. The anomalous origin of the left pulmonary artery (isolated lesion in 40% of patients) usually occurs in the presence of a right aortic arch. Very rarely, the anomalous pulmonary artery can originate from the descending thoracic aorta or from either the right or the left coronary artery. Extremely rare cases have been reported of anomalous origin of one pulmonary artery from the innominate artery, the right pulmonary artery with normal left aortic arch, and the left pulmonary artery in the presence of right aortic arch.

Associated anomalies

Left (rarely right) patent ductus arteriosus is present in 50–75% of patients. Other associated anomalies are atrial or ventricular septal defect (8–10% of patients), tetralogy of Fallot with or without absent pulmonary valve, pulmonary stenosis or atresia with ventricular septal defect, aortopulmonary window, right aortic arch (50–75% of cases with anomalous left pulmonary artery), aortic coarctation, aortic arch interruption.

Surgical options

The surgical repair can be performed either with or without cardiopulmonary bypass. The use of cardiopulmonary bypass, particularly in infants, allows adequate mobilization of the anomalous pulmonary artery, safe separation from the ascending aorta and reimplantation on the main pulmonary artery. Various surgical techniques have been reported for reimplantation of the anomalous pulmonary artery to the main pulmonary artery, posterior to the ascending aorta, including the direct anastomosis (definitely the preferred technique), an extension with either an aortic flap or an autologous pericardial patch, or the interposition of a synthetic tubular prosthesis, now practically abandoned.
**Pre-operative information**

The CT scan (Fig. 3.23.1) and MRI can provide full visualization of the pulmonary arteries and their origins, particularly of the proximal segment of the left pulmonary artery, a frequent blind spot for transthoracic and transesophageal echocardiography. The side of the aortic arch and the presence of other associated anomalies can also be visualized.

**Potential complications**

In the immediate post-operative period, episodes of pulmonary hypertension have been reported, while in the later follow-up residual or recurrent stenosis at the site of the anastomosis with the main pulmonary artery, and inhomogeneous lung perfusion have been observed with the nuclear scan.

**Post-operative follow-up**

CT scan and/or MRI can be helpful in the post-operative evaluation of surgery for hemitrunicus especially if a pulmonary artery branch stenosis is suspected. In addition to information on the morphology of the pulmonary arteries, cardiac MRI can provide information on the lung perfusion.

For post-operative evaluation of hemitrunicus, the following cardiac MRI protocol is used:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix of the “Introduction”),
- ECG-gated cine steady-state free precession and fast spin echo sequence along the long axis of both pulmonary arteries (Fig. 3.23.2 b),
- ECG-gated cine steady-state free precession and fast spin echo sequence on the axial plane to evaluate the pulmonary arteries (Fig. 3.23.2 a),

---

**Anomalous pulmonary arteries**

**Definition**

Regardless of the position of the heart within the chest and the position and origin of the great arteries, aortic and pulmonary valves normally have a single point of contact, with commissural apposition; coronary arteries almost always originate normally from the facing sinuses of Valsalva on either side of this point of commissural contact; coronary arteries do not normally originate from the nonfacing or most distant sinus. Various types of coronary artery anomalies exist, sometimes isolated or with more than one abnormal component.

**Isolated anomalous origin of a coronary artery.** From the pulmonary artery (historically called Bland-White-Garland syndrome): the anomalous coronary artery is most often the left coronary artery. Two clinical forms, infantile and adult, are recognized, representing two ends of a morphologic and pathophysiologic spectrum, which may reflect the degree of retrograde flow from the right coronary system to the anomalous left coronary artery via collateral channels; a myocardial steel-like syndrome may develop with ischemia and infarction if collateral development is not adequate. These patients may develop cardiomegaly and mitral valve regurgitation due to papillary muscle infarction.

From the wrong sinus of Valsalva (with or without intramural course): the presence of origin of the left main coronary artery or the left anterior descending coronary artery from the right sinus of Valsalva and intramural course (inside the aortic wall) is known to be malignant (= at risk of sudden death) due to compression of the vessel during or immediately after exercise. An “interarterial” course between the aortic root and the main pulmonary artery is also malignant, mainly if associated with intramural course of the coronary artery. On the other hand, a retroaortic course of the left coronary artery is most frequently (but not always) extramural and clinically benign.

From another coronary artery: there might be a single origin for the coronary arteries from the aortic root or even a double orifice for the coronary artery, but with an anomalous left anterior descending coronary artery originating from the right coronary artery and the left facing sinus giving only origin to the circumflex coronary artery.

From an additional coronary ostium: sometimes there are three coronary artery ostia, because either the conal branch of the right coronary artery originates separately from the right sinus of Valsalva, or because the left anterior descending and circumflex coronary arteries arise separately from the left sinus instead of from the main common coronary trunk.

**Anomalous course of a coronary artery.**

*Intramural course:* defined as the coronary artery running in the wall of the aorta, sharing an adventitial origin.

*Intramyoocardial course (myocardial bridging):* defined as an epicardial segment of a coronary artery that courses through the myocardium. The fact that such bridges are reported in >1% of the general population suggests that they may be a normal benign
variant. Therefore, only “severe” myocardial bridges (whose criteria are not well defined) leading to angina pectoris, myocardial ischemia or infarction are counted as pathological entities.

- **Atresia of a coronary artery orifice:** several variations are possible, although very rare:
  - atresia of the origin of the main trunk of the left coronary artery,
  - atresia or the origin of the left anterior descending coronary artery,
  - atresia of the origin of the circumflex artery,
  - atresia of the origin of the right coronary artery.

- **Coronary artery fistula:** a coronary artery fistula consists of single or multiple communication(s) between a normally distributed coronary artery or its branches, and either a cardiac cavity (= coronary-cameral fistula) or any segment of the systemic or pulmonary circulation (= coronary arteriovenous fistula); coronary artery fistula from either the right (60% of the cases) or left coronary artery (35%) or both coronary arteries (5%) is in 90–92% of patients connected to the right side of the heart, but it may be connected to one of the following: pulmonary artery, right ventricle, right atrium, coronary sinus, superior vena cava, pulmonary vein, left atrium, left ventricle, multiple sites. Congenital coronary artery fistulas may be associated (20 to 45% of cases) with a congenital heart defect.

- **Anomalous coronary artery associated with a congenital heart defect:** coronary anomalies may be associated with several other congenital heart defects, most notably transposition of the great arteries, tetralogy of Fallot and pulmonary atresia.

- **Associated anomalies**

  Ventricular septal defect, tetralogy of Fallot, pulmonary atresia, truncus arteriosus, aorto-pulmonary window, transposition of the great arteries, congenitally corrected transposition of the great arteries (= double discordance), double-chambered right ventricle, aortic valve disease, supravalvar aortic stenosis (with Williams syndrome), hypoplastic left heart syndrome, aortic coarctation.

  Particularly important is the potential association of an anomalous origin of the left coronary artery from the pulmonary artery with patent ductus arteriosus or aortopulmonary window: even if this combination is extremely rare, there are reports of death after closure of the ductus arteriosus or aortopulmonary window. Atresia of a coronary artery orifice is more frequently associated with supravalvar aortic stenosis and anomalies of the aortic or truncal valve, where excess tissue can obstruct the coronary orifice, or where the angle of origin of the coronary artery produces a valve-like obstruction. Quadricuspid aortic valves can be associated with single coronary ostium, and displacement of the left or right coronary orifice.

- **Surgical options**

  - **Anomalous origin of the left coronary artery from the pulmonary artery:**
    - ligation,
    - end-to-side anastomosis of the left subclavian artery or the internal mammary artery (= thoracic artery) to the anomalous coronary artery,
    - Takeuchi procedure (= intrapulmonary baffling technique),
    - reimplantation,
    - heart transplant.

  - **Anomalous origin of a coronary artery from the wrong aortic sinus:** the coronary artery with anomalous origin from a wrong sinus, frequently with an intramural segment, is moved to the appropriate sinus without unroofing. An alternative technique consists of a coronary artery bypass graft, preferably
with implantation of the internal mammary artery (= thoracic artery) to the anomalous coronary artery. In the presence of compression of the anomalous coronary artery between the aorta and pulmonary artery, a feasible surgical technique consists of transection of the main pulmonary artery at the level of its bifurcation, patch closure of the distal opening and reimplantation of the main pulmonary artery to the left pulmonary artery branch. This technique allows for separation of the main pulmonary artery from the aorta with elimination (or at least reduction) of coronary artery compression.

**Coronary artery fistula:** through a median sternotomy, the feeding artery of the coronary artery fistula, its course and site of insertion are identified. In rare cases where the fistula is a terminal coronary artery, surgical occlusion by means of a direct ligature can be performed without cardiopulmonary bypass. In the vast majority of patients, the surgical procedure requires cardiopulmonary bypass and includes opening of the chamber where the anomalous fistula is draining, identification of the fistula, and suture of the anomalous coronary connection; large aneurysms may require surgical resection.

**Atresia of a coronary artery orifice:** angioplasty of the origin of a coronary artery is the surgical technique used to treat the atresia of a coronary artery orifice, or to enlarge the coronary artery main stem in the presence of left main coronary artery atresia. Enlargement can be obtained on cardiopulmonary bypass with an autologous saphenous vein or pericardium patch, or with a PTFE patch.

**Pre-operative information**

Since in children with anomalous coronary arteries, the incidence of wrong diagnosis with conventional coronary angiography is reported to be as high as 50%, noninvasive techniques (echocardiography, CT and MR angiography) are considered more reliable; the favored modalities are transthoracic echocardiography in children and multidetector CT in teenagers and adults. The recent improvements of multidetector row CT for cardiac imaging, particularly with regard to spatial and temporal resolution and sophisticated ECG gating, allow motion-free, fast, accurate, detailed, contrast-enhanced cardiac imaging, offering a noninvasive alternative diagnostic tool, useful also to delineate abnormal origin and branching of the coronary arteries. However, the elevated heart rate in small children still represents a major technical limit.

The presence of a “malignant” right coronary artery can be simulated by motion artifacts in front of the aortic root imitating an anomalous right coronary artery originating from the left posterior sinus of Valsalva. These artifacts can be avoided by using retrospective ECG gating (Fig. 3.24.1). However, the use of ionizing radiation and potentially nephrotoxic agents may limit its use particularly in small children.

![Fig. 3.24.1. Anomalous right coronary artery. CT scan oblique axial view showing the anomalous origin of the right coronary artery from the left aortic sinus, with course between the great arteries (arrow) (aA ascending aorta, PT pulmonary trunk) (reproduced with permission from Goo HW, Park IS, Ko JK, Kim YH, Seo DM, Yun TJ, Park JJ, Yoon CH (2003) CT of congenital heart disease: normal anatomy and typical pathologic conditions. Radiographics 23:S147–165)
Coronary MR angiography places particularly high demands on planning, spatial resolution, high signal-to-noise ratio, and precise cardiac and respiratory motion correction. However, recent advances in hardware, MRI sequences, and motion detection techniques allow coronary MR angiography that includes volumetric acquisition of the entire heart as well as imaging of the arterial walls within a clinically acceptable scan time to be performed. As a tomographic imaging technique, MR angiography allows 3-dimensional reconstruction and omni-directional visualization of an anomalous coronary artery origin and course, thereby eliminating some problems of selective traditional coronaryography. In particular, MR angiography facilitates the differential diagnosis of “interarterial” and “intraseptal” coronary artery courses, which are very important for prognostic evaluation.

The spatial resolution of MR angiography is satisfactory in defining the course of the coronary arteries but remains limited in defining the detailed anatomy of the critically important proximal ectopic arteries, particularly in small children, where the intramural course and degree of compression inside the aortic wall can only be guessed at. Nonetheless, because of its 3-dimensional visualization abilities, MRI can clarify the acuity of the proximal coronary artery origin (tangential take-off), its location at the level of the sinotubular junction or above it, and the sinus of origin. By itself, the presence of a coronary artery with tangential origin does not necessarily mean a stenotic effect. However, it is usually associated with an intramural course, which is clearly correlated with obstruction.

Furthermore, in addition to anatomical data, cardiac MRI allows the functional consequences of coronary artery anomalies to be evaluated: the amount of shunt and flow in the case of a coronary artery fistula, and the global and regional function of the left ventricle. Myocardial ischemia can be detected by means pharmacological stress testing either with adenosine or dobutamine. Finally by means of gadolinium delayed enhancement, fibrotic areas can be detected as well.

The MRI protocol proposed for detection of coronary artery anomalies is the following:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see appendix in the “Introduction”),
- axial fast spin echo and oblique sequences at the level of aortic root followed by a series of oblique images perpendicular to the axial plane, with slice thickness 3–4 mm (Fig. 3.24.2),
- ECG-gated cine steady-state free precession sequences in 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume as illustrated in the appendix of the “Introduction”,
- fat suppressed 3-dimensional steady-state free precession pulse sequence, (breath hold for small slab, or free breathing with Navigator to allow a larger slab) parallel to the plain of each main coronary artery (Fig. 3.24.3),
- gadolinium-enhanced 3-dimensional MR angiography,
- ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending aorta and coronary fistula (when required),

Fig. 3.24.2. Intramural left coronary artery. MRI axial fast spin echo showing intramural course of the left coronary artery (arrowhead) (AO aorta)
Fig. 3.24.3. Myocardial bridging. MRI 3-dimensional steady-state free precession (a, b and c) showing myocardial bridging of the left anterior descending coronary artery (arrow) in a patient with symptomatic hypertrophic cardiomyopathy (LV left ventricle).

Fig. 3.24.4. MRI with sensitivity encoding (SENSE) technique. Whole heart coronary magnetic resonance angiography (CMRA) in healthy volunteers. a The angiograms of the left coronary artery system (LM/LAD/LCX, upper row) and b the right coronary artery (RCA, lower row) were reformatted retrospectively from a volumetric whole heart data set. A volume rendered view is shown in c. A steady-state free precession (SSFP) sequence with an additional T2 preparation pulse was employed for optimal contrast. To maintain a clinically acceptable scan time, sensitivity encoding (SENSE) in concert with partial Fourier encoding was employed, resulting in a total scan time of 4 min during free breathing. A nearly isotropic resolution (1.3 × 1.3 × 1.5 mm3) was obtained (reproduced with permission from Stehning C, Boernert P, Nehrke K (2007) Advances in coronary MR angiography from vessel wall to whole heart imaging. Magn Reson Med Sci 6:157–170).
post-gadolinium delayed myocardial enhancement may be used to evaluate potential presence of fibrotic tissue,
more recently, the use of 32-channel coil sensitivity encoding (SENSE) permits whole heart MR angiography to be performed (Fig. 3.24.4).

Pharmacological stress testing either with adenosine or dobutamine is increasingly being incorporated into the MRI protocol in patients with suspected myocardial ischemia.

### Potential complications

**Anomalous origin of the left coronary artery from the pulmonary artery.**

Takeuchi procedure: potential complications include residual or recurrent stenosis of the new coronary artery channel, with subsequent myocardial ischemia, as well as baffle leaks, residual or recurrent supravalvular pulmonary stenosis, due to the obstruction created by the space occupied by the new coronary artery channel constructed inside the main pulmonary artery. Another potential complication is injury to the aortic valve when creating the aortopulmonary window.

Reimplantation: low cardiac output with hemodynamic instability can complicate the post-operative period, particularly in patients with severely compromised myocardial function and/or operated on after late referral. Another potential complication is the obstruction of the reimplanted coronary artery, due to excessive tension, kinking or twisting of the coronary artery, with potential subsequent myocardial ischemia or infarction. Ventricular arrhythmias can accompany poor ventricular function and severe ventricular dilatation.

Angioplasty of the origin of a coronary artery: despite patch enlargement of the orifice of a coronary artery generally providing adequate coronary artery perfusion, residual or recurrent coronary artery stenosis can require re-operation, in most cases with a coronary artery bypass graft accomplished with the internal thoracic (= mammary) artery.

**Anomalous origin of a coronary artery from the wrong aortic sinus:** inadequate coronary artery perfusion can persist after surgery, as well as malfunctioning of the aortic valve, damaged by the coronary artery reimplantation.

**Coronary artery fistulas:** myocardial ischemia or infarction, recurrence of the coronary artery fistula.

**Atresia of a coronary artery orifice:** myocardial ischemia or infarction.

### Post-operative follow-up

The aim and information requested for the post-operative evaluation of anomalous coronary artery are similar that seen in the pre-operative setting, paying attention to individualize each investigation to the previously performed operative procedure and to the current clinical condition of the patient.

Definition

Double outlet right ventricle defines a heterogeneous group of cardiac malformations unified by an abnormal ventriculoarterial connection. General agreement about the definition of double outlet right ventricle is when both great arteries, or one great artery and more than half of the other originates from the right ventricle. However, as clearly demonstrated with noninvasive investigations, this definition could be misleading due to the fact that the ventriculoarterial connections, lying on different planes, could be visualized in different ways, leading to different results, depending upon the orientation plan of the examination, independent of whether echocardiography, CT scan or MRI is used (Fig. 3.25.2). According to Yves Lecompte, the classification and terminology of this complex group of patients with anomalous ventriculoarterial connection is less important than the precise pre-operative definition of the anatomic criteria useful to determine the best surgical approach. The most general definition of “malposition of the great arteries with ventricular septal defect” should be used. Nevertheless the categorization of patients with double outlet right ventricle is necessary to compare the results of different surgical treatments.

A morphological feature characteristic of the double outlet right ventricle is absence of the normal fibrous continuity between the mitral and semilunar valves (either aortic valve in the presence of ventriculoarterial concordance, or pulmonary valve in the presence of ventriculoarterial discordance), referred to the presence of a subaortic or subpulmonary conus, respectively.

The relationship between the great arteries may vary and many relative positions have been reported; more frequently they are side by side and parallel, with the aortic valve positioned to the right of the pulmonary valve.

Patients with double outlet right ventricle have been categorized accordingly to:

The type of the ventriculoarterial connection:
- concordant (85%): the pulmonary artery originates entirely from the right ventricle,
- discordant (15%): the aorta originates entirely from the right ventricle.

The position of the associated ventricular septal defect:
- subaortic ventricular septal defect (50%),
- subpulmonary ventricular septal defect (30%),
- doubly-committed ventricular septal defect (immediately underneath the semilunar valves) (10%),
- noncommitted (remote) ventricular septal defect (far from both the semilunar valves) (10%).

The type of pulmonary blood flow:
- restricted (= with pulmonary stenosis),
- unrestricted (= without pulmonary stenosis).

The most frequent combination is double outlet right ventricle with concordant ventriculoarterial connection, subaortic ventricular septal defect and obstruction to the pulmo-
nary outflow tract (so-called tetralogy of Fal- lot-type). Typical cardiac anomalies associated with this type of double outlet right ventricle are mitral stenosis and subaortic obstruction, as well as anomalous attachments (straddling) of the anterior and septal leaflets of the tricuspid valve.

The second most frequent type is double outlet right ventricle with discordant ventriculooarterial connection and subpulmonary ventricular septal defect, without obstruction to the pulmonary outflow tract (so-called Taussig-Bing malformation). Typical cardiac anomalies associated with this type of double outlet right ventricle are straddling mitral valve, subaortic obstruction and aortic coarctation.

Another combination is double outlet right ventricle with concordant ventriculooarterial connection and subaortic ventricular septal defect, without obstruction to the pulmonary outflow tract. Typical cardiac anomalies associated with this type of double outlet right ventricle are straddling mitral valve and aortic coarctation.

More rare are the combinations of double outlet right ventricle with doubly committed or with noncommitted (remote) ventricular septal defect. In patients with noncommitted (remote) ventricular septal defect, the defect is frequently of muscular or inlet (atrioventricular) type, therefore distant from both the semilunar valves. There is ventriculooarterial concordance, and pulmonary stenosis is very rare.

Associated anomalies
Dextrocardia, juxtaposition of left auricular appendages, total anomalous pulmonary venous connection, anomalous systemic venous connections, cor triatratium, mitral stenosis, cleft of the mitral valve, common atrioventricular valve, straddling mitral and/or tricuspid valve, supraineof inferior ventricles with or without criss-crossing atrioventricular connections, multiple ventricular septal defects, hypoplastic left ventricle, left ventricular outflow tract obstruction, discrete subaortic stenosis, aortic coarctation, aortic arch interruption, absent pulmonary valve, absent left pulmonary artery, and ectopia cordis have all been reported in association with double outlet right ventricle.

The origin and course of the coronary arteries are associated with the relationship between the aorta and pulmonary artery. Several variations are described, including anomalous origin of the right coronary artery from the left main coronary artery, duplication of the left anterior descending coronary artery, anomalous origin of the left anterior descending coronary artery from the right coronary artery, anomalous origin of the left circumflex artery from the right coronary artery, and single right or single left coronary artery as the most frequent anomalies.

### Surgical options

**Palliation:**
Modified Blalock-Taussig shunt can be considered in neonates with double outlet right ventricle with concordant ventriculooarterial connection, subaortic ventricular septal defect and obstruction to the pulmonary outflow tract (so-called tetralogy of Fallot-type).

Pulmonary artery banding can be considered for double outlet right ventricle with concordant ventriculooarterial connection and subaortic ventricular septal defect, without obstruction to the pulmonary outflow tract.

**Repair:** according to each different type of morphology, several surgical techniques have been reported, referring to one of the following principles:
- **intraventricular repair** connecting the left ventricle to the aorta and the right ventricle to the pulmonary artery,
- **arterial switch** operation with closure of the ventricular septal defect by a prosthetic patch connecting the left ventricle to the neoaoorta,
- **univentricular type of repair**, with end-to-side superior vena cava to pulmonary ar-
tery anastomosis (= bidirectional Glenn) followed by total cavopulmonary connection (= modified Fontan procedure).

Because the large variability of intracardiac morphologies, with various associated cardiac lesions, and the different surgical experiences, several alternative surgical options are available for each single patient, depending on the match of the individual patient with the individual surgeon.

**Intraventricular repair:** there are different types of intraventricular repair. In all of them the left ventricle is connected to the aorta and the right ventricle to the pulmonary artery, either directly or with the interposition of a conduit.

**Intraventricular tunnel repair**, suitable for the more simple type of *double outlet right ventricle with concordant ventriculoarterial connection and subaortic ventricular septal defect*, can be performed either through right atriotomy (rarely) or right ventriculotomy. Right ventriculotomy allows easier evaluation of the adequate shape and positioning of the prosthetic patch needed to connect the left ventricle with the aorta. The ventricular size and position, combined with the relationship between the diameter of the aortic valve and the distance between the tricuspid and pulmonary valve, dictate the need for enlargement of the tunnel between the left ventricle and the aorta. When needed, the ventricular septal defect is enlarged by an anterior incision, with muscular resection. The prosthetic material used to create the intraventricular tunnel is generally a prosthetic tubular prosthesis (PTFE, Dacron) about 20% larger than the aortic diameter, cut at a length equal to the distance between the anterior edge of the ventricular septal defect and the aortic annulus. Two-thirds of the entire circumference of the tubular prosthesis are used, in a manner leaving an unobstructed left ventricle to aorta tunnel, but at the same time avoiding the potential bulging of the patch to obstruct the right ventricular outflow tract.

In the presence of severe *obstruction to the pulmonary outflow tract*, a transannular patch or a biological valved conduit implanted between the right ventriculotomy and the pulmonary artery are used to relieve the obstruction. An alternative option is the Lecompte procedure (see below for details).

In *double outlet right ventricle with discordant ventriculoarterial connection and subpulmonary ventricular septal defect, without obstruction to the pulmonary outflow tract* (so-called Taussig-Bing malformation), the intraventricular tunnel is more complicated to design and accomplished. In the *Kawashima technique*, the intraventricular tunnel is positioned posterior to the orifice of the pulmonary valve, if there is enough distance between the tricuspid and pulmonary valves. If the distance between the tricuspid and pulmonary valves is inadequate, the intraventricular tunnel has to remain anterior to the orifice of the pulmonary valve. In both cases, the ventricular septal defect needs to be enlarged by anterior resection of the infundibular septum.

In patients with *double outlet right ventricle with discordant ventriculoarterial connection and obstruction to the pulmonary outflow tract*, the best surgical option is the Lecompte procedure (or REV = *Réparation à l’Etage Ventriculaire*). After right ventriculotomy and infundibular resection, the left ventricle is connected to the aorta by closure of ventricular septal defect with a straight patch; after transection and shortening of the ascending aorta and transfer of the pulmonary artery bifurcation anterior to the aorta (*Lecompte maneuver*), the right ventricle-to-pulmonary artery continuity is obtained with reimplantation of the transected pulmonary artery directly on the right ventricle to its posterior wall, while the anterior aspect is connected to the rest of the right ventriculotomy with a monocusp pericardial patch.

**Arterial switch operation:** the crucial point is the surgical approach for closure of the ventricular septal defect. The possibilities
are through right atriotomy (ideal for perimembranous and inlet defects), through the aortic valve (neopulmonary valve) after resection of the aortic buttons with the orifices of the coronary arteries (ideal for outlet types of subaortic defects), or through the pulmonary valve (neoaortic valve) (ideal for the subpulmonary type of defects). The rest of the procedure is like that for the conventional arterial switch.

An alternative surgical technique is the Bex-Nikaidoh aortic translocation, where the aortic root, including aortic valve and coronary arteries, is isolated from the right ventricle. The pulmonary artery is transected and the area between the ventricular septal defect and the proximal stump of the transected pulmonary artery is widely incised; the left ventricle is connected to the aorta with a patch roofing the opened ventricular septal defect, while the right ventricle is connected to the transected pulmonary artery like in the Lecompte procedure.

In the Taussig-Bing type of double outlet right ventricle with aortic arch obstruction, a surgical technique recently proposed (Dr. Sano) consists of the transection of the great arteries, ductus arteriosus, descending thoracic aorta, and aortic arch with aortotomy incision from the aortic arch to the distal ascending aorta, followed by creation of an aortopulmonary window, anastomosis of the descending thoracic aorta to the posterior wall of the aortic arch, anastomosis of the neoaorta to the aortic arch with rerouting of the coronary arteries (without need for coronary arteries reimplantation), and reconstruction of the neo-right ventricular outflow tract after the Lecompte maneuver.

**Univentricular type of repair:** in the presence of complicated intracardiac anatomy (e.g., the presence of inlet type of noncommitted ventricular septal defect with straddling tricuspid valve, or common atrioventricular valve, or hypoplasia of the right ventricular chamber), the biventricular type of repair is either not feasible or the associated risk is too high. In these patients, the univentricular type of repair is the preferred surgical option.

In these cases the first step is a bidirectional Glenn, followed by the modified Fontan procedure, preceded or not by a pulmonary artery banding, depending upon the presence or absence of obstruction to the pulmonary blood flow.

**Pre-operative information**

As already described above, the so-called double outlet right ventricle includes a spectrum of different types of morphology, where, in the presence of normal ventricular size, the pathophysiology and the subsequent surgical treatment depend upon the spatial relationship between the ventricular septal defect and the great arteries, the morphology and length of the ventricular outlets, and the orientation of the infundibular septum. All combinations are possible, making

![Fig. 3.25.1. Double outlet right ventricle. CT scan showing the double outlet right ventricle, ventriculoarterial discordance, ventricular septal defect (far from the aortic valve) and pulmonary stenosis (Ao aorta, LV left ventricle, PA pulmonary artery, RV right ventricle) (photograph courtesy of Dr. Mohamed Tawil)](image-url)
any classification useless and even misleading with regard to the decision-making process among the available surgical options.

Echocardiography is certainly the first and the best tool to define the anatomy in children with double outlet right ventricle, and it is fundamental in planning the surgical repair; CT scan (Fig. 3.25.1) and/or MRI (Fig. 3.25.2) are rarely required. Exceptions include patients with complex anomalies of the aortic arch and/or pulmonary arteries, aortopulmonary collaterals, anomalous systemic or pulmonary venous connections not completely defined by echocardiography.

However, as echocardiography is limited in the assessment of all the cardiac structures from a single approach, sometimes it might be difficult to determine the 3-dimensional reconstruction of the complex ventricular septal defect/outlets/great arteries. Cardiac MRI is particularly attractive for the development of stereolithographic models able to create accurate and realistic 3-dimensional models for the pre-operative assessment of such complex congenital heart defects. A virtual incision-making tool allowing arbitrary incisions to be made on 3-dimensional MRI reconstructions has already been experimentally developed, but is not yet commercially available.

When MRI is indicated to better delineate the spatial relationship between the ventricular septal defect and the ventricular outlets and, in some instances the aortic arch and pulmonary arteries, the MRI protocol proposed has already been described in the chapters on “Tetralogy of Fallot” and “Transposition of the great arteries”, respectively. In particular cases with complex ventriculoarterial connection, it can be useful to represent the heart and great arteries on the 3 main orthogonal planes to better delineate the intraventricular morphology (Fig. 3.25.3).

Fig. 3.25.2. Double outlet right ventricle. MR Angiography maximal intensity projection in the same patient delineating apparently different ventriculoarterial connections: a) the aorta seems to originate from the anterior right ventricle and the pulmonary artery from the posterior left ventricle, b) the plane is slightly rotated and both great arteries seem to be connected to the anterior right ventricle (AO aorta, LV left ventricle, PA pulmonary artery, RV right ventricle)
Fig. 3.25.3. Double outlet right ventricle. Cine MRI of heart and great arteries on the 3 orthogonal main planes: 

- a coronal plane from posterior (upper left) to anterior (lower right),
- b sagittal plane from left (upper left) to right (lower right),
- c axial plane from inferior (upper left) to superior (lower right). The great arteries are side-by-side; the left ventricle is hypoplastic, with left and posterior position; the left atrium is superior and left sided \( AO \) aorta, \( LV \) left ventricle, \( PA \) pulmonary artery, \( RV \) right ventricle.
Potential complications

**Intraventricular repair:** potential complications after intraventricular repair include residual or recurrent ventricular septal defect, residual or recurrent right and/or left ventricular outflow tract obstruction, arrhythmias, complete atrioventricular block, atrioventricular valve regurgitation.

**Arterial switch operation:** the most frequent complications are residual or recurrent right ventricular outflow tract obstruction, and residual or recurrent neoaortic valve regurgitation.

**Univentricular type of repair:** see chapter “Single ventricle”.

Post-operative follow-up

The role of cardiac CT scan and MRI after surgery for double outlet right ventricle increases in adult patients when their acoustic window for echocardiography becomes more limited. The examination strategy is tailored to the underlying morphology and the type of surgery performed. Patients with a “tetralogy of Fallot type” of double outlet right ventricle repair have similar long-term course as those after repair for tetralogy of Fallot, and the CT scan and MRI protocols have already been highlighted in the related chapter. Similarly, in those with “Transposition of the great arteries or Taussig-Bing type” (see the relative chapter) of double outlet right ventricle, the post-operative is-
sues are similar to those encountered after the Rastelli procedure (Figs. 3.25.4–3.25.6) or REV procedure (Figs. 3.25.7 and 3.25.8), respectively. Of course in these cases, it is very important to adapt and modify, if necessary, the investigation protocol to address morphologic and functional abnormalities specific to the individual patient; this requires on-line evaluation of the imaging data since previously unsuspected abnormalities may only be detected during the scan.

**Fig. 3.25.4.** Status post repair of double outlet right ventricle. a CT scan contrast angiography, axial projection, showing the valved conduit implanted between the right ventricle and the pulmonary artery, with a narrowing near the distal anastomosis (arrow). b CT scan in the same patient contrast angiography, sagittal projection, showing the valved conduit implanted end-to-side to pulmonary artery leaving open the native right ventricular outflow tract, with the measurement of the narrowing near the distal anastomosis (diameter = 5.9 mm) (AAo ascending aorta, DTA descending thoracic aorta, LPA left pulmonary artery, nRVOT native right ventricular outflow tract, RPA right pulmonary artery, RV right ventricle, SVC superior vena cava, VC valved conduit) (photographs courtesy of Dr. Mohamed Tawil)

References

**Definition**

In this fascinating cardiac malformation, the morphologically left atrium (= pulmonary venous atrium) is connected via a tricuspid valve with the morphologically right ventricle, from which originates the aorta, while the morphologically right atrium (= systemic venous atrium) is connected via a mitral valve with the morphologically left ventricle, from which originates the pulmonary artery. Therefore two discordant connections, atrioventricular and ventriculoarterial (= double discordance), occur in sequence in each side of the heart. The classical definition of “congenitally corrected transposition of the great arteries” derived from the observation that the effects of transposition of the great arteries are “corrected” by the congenital inversion of the two ventricles, with the two circulatory pathways “physiologically” in series, despite the anatomic derangements.

In these hearts an atrial situs solitus or inversus can be present, as well as superoinferior disposition of the ventricular chambers can occur, with a more or less horizontal interventricular septum. Dextrocardia is present in 25% of the cases. The ascending aorta is typically located anterior and to the left of the pulmonary artery (Figs. 3.26.1 and 3.26.2). The coronary arteries originate from the facing sinuses of the aortic valve, generally with a mirror-image distribution, following the appropriate ventricle.

**Associated anomalies**

In double discordance, probably less than 1% of individuals have no associated malformations. The most frequent and important associated lesions are ventricular septal defect (up to 80% of cases), tricuspid valve anomalies (= Ebstein-like malformation), corresponding to abnormalities of the systemic atrioventricular valve (in up to 60% of cases), pulmonary stenosis or atresia (30–50%), dextrocardia.

*Fig. 3.26.1. Double discordance. CT scan contrast angiography, axial projection, showing the aorta with anterior-left position in relationship with the pulmonary artery, and the presence of bilateral superior vena cava (arrows). The left superior vena cava is more faintly opacified because contrast material was injected in a vein of the right arm (A aorta, LPA left pulmonary artery, P pulmonary artery, RPA right pulmonary artery) (reproduced with permission from Choi BW, Park YH, Choi JY, Choi BI, Kim MJ, Ryu SJ, Lee JK, Sul JH, Lee SK, Cho BK, Choe KO (2001) Using electron beam CT to evaluate conotruncal anomalies in pediatric and adult patients. Am J Roentgenol 177:1045–1049)*
(25%) and complete atrioventricular block (12–33% of cases). Mitral valve anomalies are also quite frequent (up to 55% of cases). Straddling of an atrioventricular valve can be associated with hypoplasia of the ipsilateral ventricle.

Coronary artery anomalies potentially complicating anatomical repair have been reported in 45% of patients, including single coronary artery orifice (the most frequent coronary artery anomaly), left anterior coronary artery originating from the right coronary artery, and eccentric coronary orifices. Hypoplasia of one of the two ventricles generally occurs in the presence of a straddling atrioventricular valve (ipsilateral to the hypoplastic ventricle).

Less frequently have been reported situs inversus (with mirror-image relation), supravalvular left atrial ring, atrial septal defect, complete atrioventricular septal defect, straddling mitral valve, double outlet right ventricle, discrete subvalvular or valvular aortic stenosis (Fig. 3.26.3), patent ductus arteriosus, aortic coarctation, aortic arch interruption, aortic atresia, pulmonary atresia with intact ventricular septum, coarctation of the left pulmonary artery. The isolated atrioventricular discordance, without ventriculoarterial discordance (also called isolated ventricular inversion), has rarely been observed, generally with associated ventricular septal defect.

**Surgical options**

The surgical management of even the simple associated defects, such as ventricular septal defect or pulmonary stenosis, has been reported to be associated with much higher mortality and morbidity rates in these patients than in patients with an otherwise normal heart. From the technical point of view, the surgical approach to address the ventricular septal defect or pulmonary stenosis is difficult, and the risk of inducing a complete atrioventricular block is high. Furthermore, despite technical success, the above procedures may not result in functional improvement.

**Palliations:** the initial surgical approach in infancy can be a palliative procedure, including pulmonary artery banding in the presence of a large ventricular septal defect with pulmonary hypertension, or a modified Blalock-Taussig shunt in the presence of severe cyanosis due to pulmonary stenosis.

**Conventional repair:** depending on the age at presentation and on the specific combination of the associated lesions, conventional surgical repair of double discordance may involve tricuspid valve repair or replacement, closure of the ventricular septal defect, implantation of a biological valved conduit between the left ventricle and the pulmonary artery and pacemaker implantation.

With the conventional repair the morphologically right ventricle remains the systemic ventricle, while the morphologically right atrioventricular valve (tricuspid valve) remains the systemic valve.
**Double (= atrial and arterial) switch procedure:** because of the disappointing medium and long-term results of the conventional approach, surgical treatment in the last few years has been directed toward repair where the morphologically left ventricle and the morphologically left atrioventricular valve (mitral valve) are restored to the systemic circulation.

The following conditions are required for a double switch procedure:
- absence of major atrioventricular valve straddling,
- balanced ventricular chambers,
- adequate left ventricular function and pressure (at least 75% of the systemic right ventricle), either because of the presence of an unrestrictive ventricular septal defect or because of a previous pulmonary artery banding,
- coronary arteries not precluding transfer and reimplantation.

With the double switch procedure, the patients without pulmonary stenosis or atresia undergo atrial switch (Mustard or Senning procedure) and arterial switch (Jatene procedure), with closure of ventricular septal defect when present.

Patients with left ventricular outflow tract obstruction (= pulmonary stenosis or atresia) undergo atrial switch (Mustard or Senning procedure), closure of ventricular septal defect and implantation of an extracardiac biological valved conduit between the right ventricle and the pulmonary artery (Rastelli operation) or the direct implantation of the transected pulmonary artery on the right ventriculotomy (Lecompte procedure).

In the presence of severe heart failure, particularly biventricular failure, heart transplant has to be taken into consideration.

**One-and-half ventricular repair:** in the presence of a relatively hypoplastic ventricle, the one-and-half ventricular repair (end-to-side anastomosis of the superior vena cava to the right pulmonary artery in addition to intracardiac repair, in order to reduce the volume overload of the small/malfunctioning right ventricle) is the procedure of choice.

**Pre-operative information**

Sequential chamber localization is the fundamental first step in the diagnosis of double discordance. Accurate morphological characterization of the cardiac chambers and the great arteries is essential for the diagnosis of double discordance. The criteria to distinguish the morphologic right ventricle (functionally systemic ventricle) include course trabeculation, typical papillary muscles pattern with a septal origin as well as a vascular conus, presence of a moderator band, and more apical insertion of the atrioventricular valve (in this case the tricuspid valve) in the body of the right ventricle.

On the other hand, the morphologic left ventricle is recognized by its fine trabeculation and less apical insertion of the atrioventricular valve (in this case the mitral valve) to the septum than to the contralateral side. The aortic arch with its branches and the take-off of the coronary arteries allow recognition of the aorta, with the atypical coronary artery pattern. Identification of the short trunk and the immediate bifurcation is key for identifying the main pulmonary artery.

Echocardiographic investigation generally provides all the information required for correct diagnosis and decision making for surgery, particularly in infants and children.

However, cardiac MRI assumes an increasing role in several important pre-operative issues, mainly in older children, such as ventricular volumes and functions, morphology of the outflow tracts, relationship between ventricular septal defect and intracardiac structures, morphology of the pulmonary arteries, origin and course of the coronary arteries, and morphology and location of the auricular appendages as well, to rule out juxtaposition of the auricular appendages as well, in case anatomical correction is taken into consideration.
To achieve these goals the following cardiac MRI protocol is suggested:

- 3-plane localizing images,
- 2-dimensional axial Time-of-flight Angiography (see the appendix in the “Introduction”),
- ECG-gated cine steady-state free precession sequences in the 2-chamber, 4-chamber planes, and ventricular short axis for the quantitative assessment of both ventricular dimensions, function and stroke volume (Fig. 3.5.3) as illustrated in the appendix of the “Introduction”; 4-chamber acquisition is very informative to confirm the diagnosis of double discordance, highlighting the attachment of the atrioventricular valve septal leaflets to the septum and the different trabeculation pattern of both ventricles (Fig. 3.26.4),
- ECG-gated cine steady-state free precession sequence to visualize the left ventricular outflow tract and pulmonary valve to rule out any obstruction on the pulmonary pathway,
- ECG-gated cine steady-state free precession sequence, generally on the sagittal plane, to visualize the right ventricular outflow tract and the aorta located anterior and to the left,
- ECG-gated static 3-dimensional steady-state free precession for the evaluation of the origin and proximal course of the coronary arteries,
- ECG-gated cine steady-state free precession sequence on different oblique planes to evaluate the presence of a ventricular septal defect and its relationship to both outflow tracts (Fig. 3.26.5),
- gadolinium-enhanced 3-dimensional MR angiography for the evaluation of the great arteries, the aortic arch, and the pulmonary and systemic veins,
- ECG-gated phase velocity contrast MRI sequences perpendicular to the main pulmonary artery, ascending aorta, and pulmonary arteries, to assess flow pattern in the great vessels, mainly to quantify shunts if present. Tricuspid valve regurgitation in these patients is very common due to the presence of systemic pressure in the right ventricle and may be due to the ventricular septal shift as well, leading to a tricuspid valve regurgitation due to malfunction of the tricuspid chordae attached to the septum. This is confirmed by the observation that in patients with double discordance...
with large ventricular septal defect, where the ventricular septum is straight and not shifted to the left, tricuspid valve regurgitation is generally less progressive than in the case of low subpulmonary ventricle pressure. This hypothesis is confirmed in patients with double discordance and large ventricular septal defect after pulmonary artery banding (see section “Post-operative follow-up”, Fig. 3.26.6). Tricuspid regurgitation can be quantified by subtracting the right ventricular stroke volume from the aorta stroke volume, if the accuracy of both measurements is good.

Post-gadolinium delayed myocardial enhancement may be used to evaluate the presence of scar tissue. In case of double discordance, one major concern is the capacity of the morphologic right ventricle to sustain (lifelong) the systemic circulation due to both the characteristics of the myocardial fibers disposition and the possibility of progressive tricuspid valve regurgitation. To address this issue, in addition to assessment of right ventricular volumes and ejection fraction, it is possible to assess the contractile reserve of the systemic right ventricle during and after beta-adrenergic stimulation, taking advantage of the high accuracy of MRI compared to echocardiography because of the bizarre shape of the right ventricle. The clinical significance of such studies, even in the preoperative setting, requires more extended investigations.

In patients with double discordance, when the descending thoracic aorta is located on the contralateral side of the ascending aorta, the ascending aorta is positioned more laterally and the aortic arch is located more posterior, and as a consequence tracheal compression can be caused by the elongated aortic arch. In these cases, CT or MRI show a transversely oriented aortic arch and severe tracheal compression in the anteroposterior direction by the aortic arch. Aortic size (larger than normal), posterior position, elongation, and end-on appearance of the aortic arch are useful predictors of tracheal compression.
Fig. 3.26.6. Double discordance, status post pulmonary banding. Cardiac MRI steady-state free precession 4-chamber view in proto-systole (a) and in tele-systole (b), left ventricular outflow tract (c) and right ventricular outflow tract (d). Note in a the tricuspid lack of coaptation (headarrow) disappearing at the end of the systole (b), probably because the septum (asterisk) where the tricuspid valve chordae are attached, is shifted toward the right ventricle due to the high pressure in the left subpulmonary ventricle (AO aorta, LA left atrium, LV ventricle, PA pulmonary artery, PAB pulmonary artery banding, RA right atrium, RV right ventricle)
Fig. 3.26.7. Double discordance with ventricular septal defect, status post atrial (Senning) and arterial switch. Cine steady-state free precession (a, c, d, e) and volume rendering MR angiography reconstruction (b). No evidence of pulmonary (e) and systemic veins (c, d) baffle stenosis (AO aorta, IVC inferior vena cava, LV left ventricle, PA pulmonary artery, PVs pulmonary veins, RV right ventricle, SVC superior vena cava)
### Potential complications

**Conventional repair:** early potential complications are arrhythmias, complete atrioventricular block, residual ventricular septal defect, residual tricuspid valve regurgitation and residual right ventricular outflow tract obstruction.

In the follow-up, a substantial percentage (up to 67%) of patients treated with conventional repair develops congestive heart failure and dysfunction with morphological right ventricular failure. These complications are strongly associated with regurgitation of the morphologically right atrioventricular valve (tricuspid valve), and particularly with tricuspid valve repair or replacement.

**Double (= atrial and arterial) switch procedure:** myocardial failure with low cardiac output can occur after such a long and complicated procedure, particularly in the presence of previous surgical treatment(s). Other potential complications are the occurrence of complete atrioventricular block, residual or recurrent systemic and/or pulmonary venous obstructions (because of the atrial rerouting), residual or recurrent atrial septal defect, residual or recurrent tricuspid valve regurgitation, residual or recurrent ventricular septal defect, residual or recurrent left or right ventricular outflow tract obstruction.

### Post-operative follow-up

Cardiac MRI is particularly useful in the follow-up of these patients particularly because of the complex intracardiac anatomy and the surgical baffle, which are difficult to visualize by any other diagnostic technique.

Post-operatively, cardiac MRI provides quantitative evaluation of the left and right ventricular mass, size and function, and also the presence of residual intracardiac shunts and the presence and degree of potential tricuspid valve regurgitation. Thus, after palliation with pulmonary artery banding in the presence of double discordance, cardiac MRI can beautifully show the tricuspid (systemic) leaflet coaptation throughout the systole demonstrating its variation depending upon the ventricular septal shifting (Fig. 3.26.6).

Cardiac MRI is also able to rule out any baffle obstruction or leak after atrial rerouting (Mustard or Senning procedures) as well as to visualize the outflow tracts (Fig. 3.26.7).

After arterial switch (Jatene procedure), because of the potential complication of neoaortic valve regurgitation, cine MRI is useful to visualize the aortic root and leaflets and to detect the mechanisms of aortic valve regurgitation, as well as to monitor its progression by means of serial assessment of the aortic flow and regurgitation fraction.

In patients with pre-operative tracheal compression, the postoperative investigation with CT scan should demonstrate decreased size of the aorta and ascending aorta restored to its anterior position, with reduction or disappearance of the tracheal compression.

### References

**Definition**

In patients with incomplete lateralization of thoracic and visceral organs, the atrial appendages are also not lateralized. Thus, in the vast majority of these patients both atrial appendages present with similar internal and external morphology, characteristic of either the right or the left atrial appendage. Atrial isomerism is the designation for hearts with bilaterally right atrial appendages (Fig. 3.27.1) or bilaterally left atrial appendages.

Anomalous systemic venous connections are generally associated with atrial isomerism.

These so-called heterotaxic syndromes are characterized by failure of many “right-left” differentiations, leading to situs inversus or ambiguity in the visceroauthria atrial situs, along with anomalies of systemic and/or pulmonary venous connections (Fig. 3.27.2).

In patients with *left atrial isomerism* the infrahepatic portion of the inferior vena cava is frequently (75% of the cases) absent (= inferior vena cava interruption), and the venous return from the lower part of the body reaches the superior vena cava via the azygos vein (= azygos continuation) (Fig. 3.27.3) or via the hemiazygos vein (= hemiazygos continuation) emptying into either a right-sided superior vena cava or into a persistent left superior vena cava. Inferior vena cava interruption has never been observed in *right atrial isomerism*.

![Fig. 3.27.1. Right atrial isomerism. Cardiac MRI time of flight, maximal intensity projection reconstruction showing two morphologic right atria with two symmetrical right auricular appendages (asterisk) and wide interatrial communication (arrows) (mRA morphologic right atrium)](image)

![Fig. 3.27.2. Situs inversus. Cine MRI showing situs inversus with dextrocardia, right atrial isomerism, atrioventricular septal defect, total anomalous pulmonary venous connection. Note the common atrium and the common atroventricular valve](image)
In patients with right atrial isomerism the inferior vena cava and the abdominal aorta may run along the same side of the spine (Fig. 3.27.4); the right and the left hepatic veins may enter the ipsilateral sides of the common atrium, remaining separate from the connection of the inferior vena cava.

Persistent left superior vena cava is present in 50% of patients with right atrial isomerism and in 70% of patients with left atrial isomerism, and in both situations, particularly in right atrial isomerism, it can be connected to the upper left side of the left atrium instead of the coronary sinus.

The coronary sinus orifice can often be absent, more frequently in right atrial isomerism than in left atrial isomerism.

Abnormalities of the pulmonary veins are also common in both left and right atrial isomerism; total anomalous pulmonary venous connection to the superior or inferior vena cava is more frequent in right atrial isomerism (in 40% of these patients with obstruction to the pulmonary venous return), whereas anomalous pulmonary venous connection into the same side of the atrium as the systemic venous drainage is more frequent in left atrial isomerism (generally unobstructed).

The atrial septum and ventricular septum are very rarely normal in patients with atrial isomerism; a common atrium is present in about 50% of the cases, atrioventricular septal defect in about 80% of cases, with most patients having a common atrioventricular orifice, and various types of ventricular septal defect can be present, in the vast majority of cases of atrioventricular type.

Frequently, there is outflow obstruction to pulmonary arterial blood flow at the valvular and/or subvalvular level. Pulmonary atresia is slightly more common in right atrial isomerism, whereas pulmonary stenosis is more common in left atrial isomerism.

Ventriculoarterial discordance is very frequent (75–90% of cases).
Pulmonary artery anomalies are not rare, particularly when there is pulmonary atresia with the ductus arteriosus as the only source of pulmonary blood flow. After closure of the ductus arteriosus, a “coarctation” commonly develops at the origin of the left pulmonary artery, at the insertion of the ductus arteriosus.

The branching pattern of the pulmonary arteries generally assumes one of two forms, depending on whether left or right atrial isomerism is present. In right atrial isomerism, both right and left pulmonary arteries tend to look like a normal right pulmonary artery (= two right pulmonary arteries), with the bronchus for the upper lobe being above the descending lower pulmonary arteries (PA pulmonary artery, UL upper bronchus) (reproduced with permission from Goo HW, Park IS, Ko JK, Kim YH, Seo DM, Yun TJ, Park JJ, Yoon CH (2003) CT of congenital heart disease: normal anatomy and typical pathologic conditions. Radiographics 23:S147–165).

In contrast, in left atrial isomerism, the bronchus is below the pulmonary artery at the hilum (hypoarterial bronchus), as is the case for a normal left pulmonary artery (= two left pulmonary arteries) (Fig. 3.27.6).

Atrial isomerism generally corresponds to thoracic isomerism; therefore, in right atrial isomerism both lungs tend to be trilobed (= two right lungs), whereas in left atrial isomerism both lungs tend to be bilobed (= two left lungs).

Finally, asplenia is more commonly present in right atrial isomerism, whereas polysplenia is more frequently associated with left atrial isomerism. These features have contributed to the general rule (with several exceptions) that patients with right atrial isomerism tend to have bilateral “right-sidedness” (asplenia), whereas those with left atrial isomerism tend to have bilateral “left-sidedness” (polysplenia).

Because of the extreme morphological variability within the cases with atrial isomerism, the term “heterotaxy” has been suggested to define the presence of any of the numerous possible anomalies of lateralization.

**Associated anomalies**

- **Left isomerism**: polysplenia, anomalous systemic and/or pulmonary venous connection are very frequent, with interruption of the inferior vena cava and azygos continuation as the most frequent (56–92% of cases), followed by anomalous pulmonary venous connection (56%) that in a certain percentage of
patients is potentially obstructive, common atrioventricular valve (46–49%), common atrium (38%), cor triatriatum (30%), pulmonary atresia or stenosis (28%), aortic coarctation (16%), congenital atrioventricular block (7%).

**Right isomerism:** asplenia, valvular and subvalvular pulmonary stenosis or pulmonary atresia are predominant (89% of cases), followed by discordant ventriculoarterial connection (72–75%) either with transposition of the great arteries or double outlet right ventricle, atrioventricular septal defect (72%) with or without a common atrium, single ventricle (55%), extracardiac total anomalous pulmonary venous connection (50%), persistent left superior vena cava, bilateral right auricular appendages (20%).

**Surgical options**

**Palliation:** pulmonary artery banding or modified Blalock-Taussig shunt in the presence of increased or reduced pulmonary blood flow, respectively.

**Biventricular repair:** in the presence of anomalous systemic and/or pulmonary venous connection(s) a complex interatrial baffle (pericardium, Teflon, PTFE) is very frequently required to obtain adequate re-routing of the systemic and pulmonary venous returns. In the presence of persistent left superior vena cava, particularly when it is connected to the left atrium, the extracardiac connection of the left superior vena cava either to the right superior vena cava or to the right auricular appendage can simplify the partitioning of the atrial chambers. The techniques to repair a atrioventricular or ventricular septal defect have been described in the relative chapters.

**Univentricular repair**

- Bidirectional Glenn or hemi-Fontan.
- Modified Fontan or total cavopulmonary connection.

CT and MRI investigations can show the presence of multiple abnormally positioned spleens (polysplenia), right-sided stomach, left-sided liver, short pancreas and dextrocardia.

CT and MRI studies are particularly helpful in defining the presence and location of anomalous hepatic, pulmonary and/or systemic venous connections. Important for surgical decision making and the management of cardiopulmonary bypass is the identification of the connections between the hepatic and pulmonary veins and the atria, and the association of other anomalous systemic venous connections such as the interrupted left-sided inferior vena cava withazygos continuation.

To achieve these goals in such patients, a MRI 2-dimensional axial time of flight sequence from below the diaphragm up to the neck (see the appendix in the “Introduction”) is particular useful in order to define with high spatial resolution both the pulmonary and systemic venous connections and the cardiac and great arteries complex arrangement, without using contrast medium, ready to be post-processed (Fig. 3.27.1).

Airway morphology is better demonstrated by CT scan (Figs. 3.27.5 and 3.27.6); however a
targeted frontal fast spin echo slice, or even localizer, can fully delineate the bronchial sidedness (Fig 3.27.7).

A complete protocol to evaluate the frequently associated anomalies is listed in detail in other chapters (see particularly the chapters “Single ventricle” and “Anomalous systemic venous connections”).

### Potential complications

The main differences with regard to the complications compared to the patients with functionally univentricular hearts without isomerism are the following:

- after bidirectional Glenn (see chapter “Single ventricle”), there is a higher incidence of prolonged pleural effusions and chylothorax,
- after modified Fontan or total cavopulmonary connection (see chapter “Single ventricle”), there is a higher incidence of prolonged pleural effusions, supraventricular arrhythmias, pulmonary arteriovenous malformations and venovenous collaterals (particularly after Kawashima operation).

### Post-operative follow-up

For the post-operative follow-up after univentricular type of surgery see the relative chapter (“Single ventricle”), paying particular attention to the associated anomalies.

This chapter considers the two most frequent anatomical situations with slings and/or rings: pulmonary artery sling and vascular ring.

**Pulmonary artery sling**

**Definition**

In pulmonary artery sling (= anomalous left pulmonary artery), the left pulmonary artery originates extrapericardial from the posterior aspect of the right pulmonary artery, encircles the right main bronchus and courses right-to-left, posterior to the distal tracheal bifurcation and anterior to the esophagus, before entering the hilum of the left lung.

The ligamentum arteriosum is posterior to the aorta from the origin of the right pulmonary artery, superior to the left main bronchus, effectively creating a vascular ring (or sling) around the trachea but not around the esophagus.

Approximately 50% of patients with pulmonary artery sling have complete cartilaginous tracheal rings: the posterior membranous component of the trachea is absent, and the tracheal cartilages, rather than being U shaped, are O shaped. As a consequence, the trachea is often narrower than normal. The complete rings may be localized to the region where the sling passes around the trachea, although often they extend the entire length of the trachea, creating a long-segment tracheal stenosis (= sling-ring complex). In the area where the sling passes around the trachea, there is likely to be tracheal compression resulting in important functional stenosis. With prolonged duration of airway compression, tracheomalacia and/or bronchomalacia can be a severe consequence.

Bronchus suis (= “pig bronchus”), consisting of separate high origin of the epiarterial bronchus to the right upper lobe from the trachea, is also relatively frequently associated with pulmonary artery sling.

Congenital heart defects are present in 50% of patients with pulmonary artery sling, most commonly atrial septal defect, ventricular septal defect, patent ductus arteriosus, persistent left superior vena cava, scimitar syndrome (see chapter “Partial anomalous pulmonary venous connection”). Extremely rare is the association with tricuspid atresia, single ventricle, tetralogy of Fallot, transposition of the great arteries, aortic arch anomalies.

Other anomalies in the arterial supply to one or both lungs are also associated with this malformation, e.g. the anomalous left pulmonary artery only supplying the left upper lobe with normal pulmonary artery supply to the left lower lobe, or partial anomalous supply to the right upper lobe from an anomalous left pulmonary artery.

**Surgical options**

Reimplantation of the anomalous left pulmonary artery is the treatment of choice, with or without tracheal reconstruction according to the degree, extent and duration of the airway involvement.
In the presence of associated malformations of the upper airway, its surgical treatment must be absolutely performed during the same operation for the vascular lesion.

Division of the anomalous left pulmonary artery at the origin and its mobilization and subsequent reimplantation into the main pulmonary artery anterior to the trachea can be accomplished either with or without cardiopulmonary bypass. The mobilization of the pulmonary artery is enhanced by the division of the ligamentum arteriosum. The procedure of reimplantation of the anomalous left pulmonary artery has been reported via left or (very rarely) or right thoracotomy, but the preferred approach is through a median sternotomy to allow better mobilization of the pulmonary artery and the choice between the reimplantation with or without cardiopulmonary bypass, and also for simultaneous tracheal reconstruction (of course with cardiopulmonary bypass) in the presence of complete tracheal rings with or without long-segment tracheal stenosis.

With regard to tracheal reconstruction, several techniques have been adopted for circulatory ring stenosis.

- **Resection** is the procedure of choice for short stenosis (<1/3 of the tracheal length) without involvement of the carina or the main bronchi.
- For long segment tracheal stenosis, the technique of slide tracheoplasty, feasible even in infants in the presence of very long segment tracheal stenosis, has been demonstrated to provide the most reliable and consistent early and long-term results.
- Tracheoplasty with pericardial patch, homograft, prosthetic patch or costal cartilage has been reported in a few cases with very inconsistent results.

### Pre-operative information

Artifacts introduced by the lungs and airway negatively affect the ability of ultrasound to accurately assess the relationship between the airways and great vessels and aortic arch, while angiography fails to show the esophagus and airways.

In contrast to echocardiography and angiography, both CT scan and MRI can simultaneously define the anatomical details of both the airway and the vascular structures, facilitating diagnosis and surgical planning.

While CT and MRI seem to be equivalent to conventional cardiac catheterization and angiographic techniques for detecting vascular abnormalities, CT scan is more accurate than MRI in assessing the morphology of the airway (complete tracheal rings and extent of tracheal stenosis) and for the diagnosis of potentially life-threatening complications, such as tracheal, bronchial or esophageal compression.

CT scan can delineate the position of the left pulmonary artery arising from the right pulmonary artery, encircling the trachea, and reaching the hilum of the left lung coursing anteriorly to the esophagus and the aorta (Fig. 3.28.1); furthermore, it shows the presence of complete tracheal rings and the level and extent of tracheal stenosis (Fig. 3.28.2).

In patients with congenital heart defects, the posterior displaced ascending aorta may compress the main bronchus on the side of the aortic arch and right pulmonary artery against the descending thoracic aorta or spine. Even if the bronchial compression is mild with tolerable airway symptoms, these patients must be observed closely.

In these cases, the CT shows on the axial image a significantly larger retrosternal space, smaller interaortic distance, smaller aorto-vascular distance, and bronchial stenosis quantifiable on reformatted images perpendicular to the mainstem bronchi. However, the use of ionizing radiation limits the utilization of CT scan in children.

On the other hand, MRI can provide information on the relationship between the aorta and its branches and trachea and bronchi (Fig. 3.28.3), and phase velocity contrast acquisition of both pulmonary arteries can also provide information on the pulmonary blood flow distribution.
Potential complications

Residual or recurrent stenosis (also with reported occlusion) at the origin of the reimplanted left pulmonary artery, residual or recurrent airway obstruction, tracheomalacia, recurrent respiratory infections.

Post-operative follow-up

Both CT scan and MRI can evaluate the surgical results and detect the presence of potential complications with the same considerations followed for the pre-operative investigation.

Fig. 3.28.1. Pulmonary artery sling. a CT scan, axial projection, showing the left pulmonary artery arising from the right pulmonary artery, encircling the trachea, and reaching the hilum of the left lung coursing anteriorly to the esophagus and the aorta. b Contrast MRI, axial projection, in the same child showing the left pulmonary artery arising from the right pulmonary artery, encircling the trachea, and reaching the hilum of the left lung coursing anteriorly to the esophagus and the aorta. c Lateral view of the 3-dimensional reconstruction of the CT angiography in the same patient showing the absence of origin of the left pulmonary artery from the main pulmonary artery, and its origin (arrow) from the right pulmonary artery (star) (AAo ascending aorta, DTAo descending thoracic aorta, Es esophagus, LPA left pulmonary artery, MPA main pulmonary artery, RPA right pulmonary artery, Sp spine) (reproduced with permission from Corno AF (2004) Congenital Heart Defects. Decision making for surgery. Volume 2, Springer)
Vascular ring

**Definition**

Various congenital vascular anomalies can result in airway compression at the level of the trachea or of the main bronchi (mostly the left), and esophageal compression, because of the presence of a complete or incomplete vascular ring constituted by the aortic arch and its branches. Generally a vascular ring is due to the presence of a double aortic arch or a right aortic arch. However a right aortic arch may occur without forming a vascular ring depending upon branching of brachiocephalic vessels and location of the ductus arteriosus.

**Frequent forms:**

- **Double aortic arch:** one of the two most common forms of complete vascular rings; the trachea and esophagus are completely encircled by connected segments of the aortic arch and its branches. Various forms of double aortic arch exist: both arches may be patent, or an atretic segment may exist at one of several locations in either arch. The right arch, generally dominant (in 50–75% of patients), gives origin to the right common carotid and right subclavian arteries either as an innominate artery or as two separate vessels. The left arch, which gives origin to the left common carotid and left subclavian arteries, is patent in the majority of patients, but it may be hypoplastic or atretic beyond the origin of either the left common carotid (rarely) or the left subclavian artery (more frequently) (Figs. 3.28.4 and 3.28.5). In 15–25% of patients the left arch is dominant, and in these cases the right arch is almost always patent, while in 15–25% of patients the right and left aortic arch present with almost equal size.

- **Right aortic arch with anomalous origin of the left subclavian artery and left ductus arteriosus or ligamentum arteriosum:** a
**Fig 3.28.3.** Pulmonary artery sling. Fast spin echo MRI supero-inferior axial scan (a) and para-axial scan, fast spin echo MRI (b), and 3-dimensional volume rendering reconstruction (c) of anomalous origin of the left pulmonary artery encircling the right bronchus. The left pulmonary artery presents an anterior compression by the distal trachea and proximal bronchi, posterior by the spine. Axial time of flight image of both pulmonary arteries (d). Note its different caliber corresponding to different lung perfusion assessed by phase velocity contrast acquisition (68% of pulmonary perfusion to the right and 32% to the left pulmonary artery) (AO aorta, LPA left pulmonary artery, RPA right pulmonary artery, RVOT right ventricular outflow tract)
Fig. 3.28.4. Double aortic arch. CT scan, contrast angiography volume rendering reconstruction, viewed from above (a) and posterior coronal view (b), showing the double aortic arch, with the dominant right arch giving origin to the right carotid and right subclavian arteries and the left arch, from which the left carotid and left subclavian arteries originate and which is hypoplastic (arrow) beyond the origin of the left subclavian artery (AAo ascending aorta, DTA descending thoracic aorta, LAoA left aortic arch, LCA left carotid artery, LSA left subclavian artery, RAoA right aortic arch, RCA right carotid artery, RSA right subclavian artery) (photographs courtesy of Dr. Mohamed Tawil and Dr. Cinzia Crawley)

Fig. 3.28.5. Double aortic, with atretic left arch. MR angiography volume rendering reconstruction, posterior view, showing the hypoplastic left arch with atretic end segment (arrow) (DTA descending thoracic aorta, LAA left aortic arch, LCA left carotid artery, LSA left subclavian artery, RAA right aortic arch, RCA right carotid artery, RSA right subclavian artery) (photograph courtesy of Dr. Mohamed Tawil)
right aortic arch gives origin, in sequence, to the left common carotid, the right common carotid, the right subclavian, and the left subclavian arteries. The left subclavian artery, last branch originating from the aortic arch, passes behind the esophagus and then gives origin to the ductus arteriosus or ligamentum arteriosum, which passes anteriorly to connect to the proximal left pulmonary artery, thereby completing the vascular ring.

- **Right aortic arch with mirror-image branching and left retroesophageal ductus arteriosus or ligamentum arteriosum:** a right aortic arch gives origin, in sequence, to the left innominate artery (left common carotid with left subclavian), the right common carotid, and the right subclavian artery. The final branch, often arising from a prominent ductus diverticulum, is a patent ductus arteriosus or ligamentum arteriosum that passes leftward behind the esophagus and then anteriorly to reach the left pulmonary artery.

- **Anomalous innominate artery:** the innominate artery originates more posterior than usual from the left aortic arch and crosses posteriorly the trachea, compressing the anterior tracheal wall (**innominate artery compression syndrome**).

- **Pulmonary artery sling:** see above.

**Rare forms:**

- **Right or left retroesophageal aortic arch.**

- **Right aortic arch with anomalous left subclavian artery with or without aortic coarctation:** this combination is technically not a complete vascular ring, but it may cause symptoms similar to a ring because of the presence of a right-sided patent ductus arteriosus or ligamentum arteriosum, contributing to the formation of an incomplete vascular ring. The esophageal compression can be more severe in the presence of aneurysmal dilatation of the anomalous left subclavian artery origin (= Kommerel diverticulum) (Figs. 3.28.6 and 3.28.7).

---

**Fig. 3.28.6.** Right aortic arch with diverticulum of Kommerell and anomalous origin of the left subclavian artery. **a** CT angiography volume rendering reconstruction viewed from above showing the right aortic arch and the anomalous left subclavian artery originating from the Kommerell diverticulum. **b** CT angiography in the same patient volume rendering reconstruction anterior view showing the right aortic arch and the anomalous left subclavian artery originating from the Kommerell diverticulum (AAo ascending aorta, DTAo descending thoracic aorta, KD Kommerell diverticulum, LCA left carotid artery, LSA left subclavian artery, RAA right aortic arch, RCA right carotid artery, RSA right subclavian artery) (photographs courtesy of Dr. Mohamed Tawil)
Situs inversus with left aortic arch and right ligamentum arteriosum.

Dominant left aortic arch, mirror-image branching, right descending aorta, and atretic right aortic arch: a dominant left aortic arch is extremely rare: the arch vessels arise normally from the normal-sized left aortic arch, while the right arch is atretic.

Left aortic arch, right descending aorta, and right-sided ligamentum arteriosum to right pulmonary artery: the reported branching sequence from the left aortic arch is the right common carotid, left common carotid, left subclavian, and, finally, right subclavian as a fourth branch from the proximal descending aorta.
Left aortic arch, anomalous right subclavian artery originating from a Kommerell diverticulum: this combination can present with esophageal compression due to the anomalous position of the right subclavian artery (Fig. 3.28.8).

A vascular ring is generally an isolated cardiac malformation, with ventricular septal defect and tetralogy of Fallot probably the most common associated anomalies. Very rarely it can be associated with anomalous left subclavian artery, left or right patent ductus arteriosus, aortic coarctation, univentricular heart, pulmonary atresia with ventricular septal defect (unusual), double outlet right ventricle, truncus arteriosus, or transposition of the great arteries.

Since the major clinical impact of the presence of a vascular ring in children is tracheal compression, altered tracheal geometry, e.g., smaller dimensions (area, shorter and longest diameters), has been demonstrated in all symptomatic children with vascular rings compared with asymptomatic children.
Esophageal compression can be associated with airway compression, while esophageal atresia is sometimes found in association with double aortic arch.

### Surgical options

The vascular ring is divided through a left thoracotomy. After division, the two stumps generally retract briskly, indicating the tension with which the ring had been surrounding the esophagus and trachea. In all cases the ligamentum arteriosum or the patent ductus arteriosus must also be divided. Frequently, there are additional fibrous strands passing across the esophagus and/or the trachea, and all these have to be divided to completely relieve compression. In the rare case requiring an approach through a right thoracotomy, the same principles are applied. The technique of video-assisted thoracoscopic division has recently been developed as an alternative approach for dividing the vascular ring.

In the case of persistent compression of trachea and/or main bronchus by the aorta or a pulmonary artery branch, “arteriopexy” is performed by suturing the retroesophageal aortic segment to the prevertebral fascia or through the sternum; “extension” of the aorta or the pulmonary artery by a tubular prosthesis may be necessary.

In the presence of innominate artery compression syndrome, the approach is through a right anterior thoracotomy with suspension of the innominate artery to the posterior aspect of the sternum; an alternative technique is the transection of the innominate artery at the origin and its reimplantation on the aorta in a more proximal position.

In the presence of right aortic arch with anomalous left subclavian artery originating from a Kommerell diverticulum, the ligamentum arteriosum is divided and the anomalous origin of the left subclavian artery is disconnected from the aneurysmal origin and reimplanted end-to-side of the left carotid artery.

In the presence of associated intracardiac anomalies requiring simultaneous repair with cardiopulmonary bypass through a median sternotomy, the division of the vascular ring is performed during the same procedure from a frontal approach, also advisable in the presence of associated tracheal or esophageal lesions requiring simultaneous surgical treatment.

### Pre-operative information

While barium esophagography and echocardiography can accurately determine side of the aortic arch and presence of a vascular ring in the majority of cases, neither modality can reliably delineate the optimal site for division of a ring, particularly in those cases with atretic or hypoplastic segments. Therefore, the surgeon is required to do more extensive dissection to obtain a complete intraoperative diagnosis and to find the best location for division. It is also noteworthy that errors in determining arch sidedness from barium swallow or echocardiography are not that rare. Precise definition of arch anatomy, such as that provided by CT scan and MRI, is superior to the aforementioned techniques as well as to the more invasive angiographic methods.

As for the pulmonary artery sling, CT scan and MRI can simultaneously define the anatomical details of both the airway and the vascular structures, facilitating the diagnosis and the surgical planning. In patients with congenital heart defects, the posterior displaced ascending aorta may compress the main bronchus on the side of the aortic arch and right pulmonary artery against the descending thoracic aorta or spine. In these cases, the CT shows on the axial image a significantly larger retrosternal space, smaller interaortic distance, smaller aortospinal distance, and bronchial stenosis quantifiable on reformatted images perpendicular to the mainstem bronchi.

The aims of the protocol for MRI imaging the aortic arch or pulmonary arteries and...
related structures are: 1) rapid identification of the basic arch anatomy or pulmonary arteries; 2) determination of tracheobronchial compression and its relationship to vascular structures; 3) optimal imaging of the aortic arch to determine the ideal site for division in the presence of a vascular ring.

- **2-Dimensional imaging:** simple transverse/axial imaging from a level in the neck just below the larynx, down to the level of the diaphragm, allows identification of the trachea and esophagus. Any area of narrowing or distortion of the nearly circular trachea is noted by fast spin echo static images thanks to their better contrast and resolution. Each arch vessel is followed from its respective termination down to the level of the aortic arch. If time permits, simple coronal imaging affords rapid cross-sectional imaging of the aortic arch(es) on either side of the trachea, which is helpful in deciding which arch is larger in case of double aortic arch. This view is also useful in recognizing a diverticulum in vessels running more vertically than horizontally. A series of simple sagittal images is particularly useful for assessing the linear extent and degree of tracheal narrowing.

- **3-Dimensional imaging:** after 2-dimensional imaging in one or more standard planes, gadolinium injection is performed to provide a 3-dimensional shaded surface display of the aorta or pulmonary arteries, facilitating the decision-making process for the best approach and position to divide the vascular ring. The other application of 3-dimensional imaging is to allow curved cuts through the great vessels for cases where tortuosity obscures areas of narrowing. By essentially reslicing them along their major axis, areas of stenosis or hypoplasia become more evident.

- **Flow assessment:** in cases of double aortic arch with similar size, velocity mapping in the two arches will show which has the lesser blood flow and therefore would be the better one to divide.

- **Potential complications**

Since in infants with severe respiratory symptoms, there is likely to be an element of tracheo/bronchomalacia associated with longstanding compression by the vascular ring during in utero development, it should be anticipated that all respiratory symptoms will not be immediately relieved, even after complete relief of the external airway compression. Nevertheless, residual or recurrent airways obstruction is possible, as well as recurrent respiratory infections, chylothorax (lesion to the thoracic duct), diaphragmatic paralysis (injury to the phrenic nerve) or vocal cord paralysis (injury to the recurrent laryngeal nerve).

- **Post-operative follow-up**

As for the pulmonary artery sling, both CT scan and MRI can evaluate the surgical results and detect the presence of potential complications with the same considerations followed for the pre-operative investigation.
